α_2-Agonists. Epidural clonidine can prolong sensory block to a greater extent than motor block. The mechanism appears to be mediated by the opening of potassium channels and subsequent membrane hyperpolarization[270] rather than an α_2-agonist effect. The addition of clonidine reduces both epidural local anesthetic and opioid requirements.[271-273] Other benefits of clonidine may include a reduced immune stress and cytokine response.[274] Epidural clonidine does have a variety of side effects including hypotension, bradycardia, dry mouth, and sedation. The cardiovascular effects may be greatest when clonidine is administered in the epidural space at the thoracic level.[275] In preliminary studies, epidural dexmedetomidine has also been shown to reduce intraoperative anesthetic requirements, improve postoperative analgesia, and prolong both sensory and motor block.[276]

Other Drugs. Conflicting reports exist regarding the benefit of epidural ketamine and whether it is neurotoxic.[277-279] Epidural neostigmine provides labor analgesia before local anesthetic infusion without causing respiratory depression, hypotension, or motor impairment.[280] Midazolam, tramadol, dexamethasone, and droperidol have also been studied but are not commonly used.

Carbonation and Bicarbonate. Many local anesthetic preparations have a pH between 3.5 and 5.5 for chemical stability and bacteriostasis. At these low pHs, a higher proportion of the drug is in the ionized form and is therefore unable to cross nerve membranes to reach the internal binding site on sodium channels. Both carbonation of the solution and adding bicarbonate have been used in an attempt to increase the solution pH, and therefore the nonionized free-base proportion of local anesthetic. Although carbonation may theoretically increase the speed of onset and quality of the block by producing more rapid intraneural diffusion and more rapid penetration of connective tissue surrounding the nerve trunk,[281,282] available data suggest that there are no clinical advantages for carbonated solutions.[235,283]

EPIDURAL TECHNIQUE

Preparation

Patient preparation as previously described for spinal anesthesia must equally be applied to epidural anesthesia, namely consent, monitoring, and resuscitation equipment, intravenous access, and choosing the patient and drugs appropriately depending on comorbidities and the nature of surgery. Sterility is arguably even more important than spinal anesthesia because a catheter is often left in situ. The extent of the surgical field must be understood so that the epidural may be inserted at the appropriate level—that is, the lumbar, low-, mid-, or high-thoracic, or less commonly, cervical.[26] A variety of epidural needles have been used for epidural anesthesia, but Tuohy needles are most common (Fig. 45.8). These needles are usually 16- to 18-g in size and have a 15- to 30-degree curved, blunt "Huber" tip designed to both reduce the risk of accidental dural puncture and guide the catheter cephalad. The needle shaft is marked in 1-cm intervals so that depth of insertion can be identified. The catheter is made of a flexible, calibrated, durable, radiopaque plastic with either a single end hole or multiple side orifices near the tip. Several investigators have found that multiple-orifice catheters are superior, with a reduced incidence of inadequate analgesia.[284-286] However, the use of multiorifice catheters in pregnant women resulted in a more frequent incidence of epidural vein cannulation.[287]

The method of identifying the epidural space must also be predetermined. Most practitioners use a loss-of-resistance technique to either air or saline, rather than the hanging drop technique, both of which are described later. If a loss-of-resistance technique is used, an additional decision about the type of syringe (i.e., glass vs. low-resistance plastic and Luer-Lok vs. friction hub) is required.

Position

The sitting and lateral decubitus positions necessary for epidural puncture are the same as those for spinal anesthesia (see also Chapter 62). As before, inadequate positioning of the patient can complicate an otherwise meticulous technique. Shorter insertion times occur in the sitting position for thoracic epidurals compared with the lateral decubitus position, but ultimately, success rates are comparable.[288] As with spinal anesthesia, epidurals are performed with the patient awake.[76]

Projection and Puncture

The level of needle insertion depends on the location of surgery (Table 45.7). Important surface landmarks include the intercristal line (corresponding to the L4-L5 interspace), the inferior angle of the scapula (corresponding to the T7 vertebral body), the root of the scapular spine (T3), and the vertebra prominens (C7). Ultrasonography may be useful to identify the correct thoracic space[233]; it is less commonly used for thoracic epidural insertion, however, because the acoustic shadows make visualization of landmarks such as the ligamentum flavum and intrathecal space more difficult.[289] A variety of different needle approaches exist: midline, paramedian, modified paramedian (Taylor approach), and caudal.

A midline approach is commonly chosen for lumbar and low thoracic approaches. After local anesthetic infiltration of the skin, the nondominant hand can be rested on the back of the patient, with the thumb and index finger holding the needle hub or wing. The angle of approach should be only slightly cephalad in the lumbar and low-thoracic regions, whereas in the midthoracic region, the approach should be more cephalad because of the significant downward angulation of the spinous processes (Fig. 45.9). In a controlled fashion, the needle should be advanced with the stylet in place through the supraspinous ligament and into the interspinous ligament, at which point the stylet can be removed and the syringe attached. If it is in the correct location, the needle should rest firmly in the tissues. Some advocate needle placement in the ligamentum flavum for both the loss-of-resistance and hanging-drop methods before attaching the syringe, but this may be difficult, particularly for novices; however, this may allow an improved appreciation of epidural anatomy for the operator. If the needle is merely inserted into the supraspinous ligament and then loss-of-resistance or hanging-drop insertion is begun, there is an increased chance of false loss-of-resistance, possibly because of defects in the interspinous ligament.[290] Such false-positive rates can be as high as 30%.

Air or saline are the two most common noncompressible media used to detect a loss-of-resistance when identifying the epidural space. Each involves intermittent (for air) or constant (for saline) gentle pressure applied to the bulb of the syringe with the dominant thumb while the needle is advanced with the nondominant hand. A combination of air and saline may also be used, incorporating 2 mL of saline and a small (0.25 mL) air bubble. Usually the ligamentum flavum is identified as a tougher structure with increased resistance, and when the epidural space is subsequently entered, the pressure applied to the syringe plunger allows the solution to flow without resistance into the epidural space. There are reports that air is less reliable in identifying the epidural space, results in a higher chance of incomplete block, and may also cause both pneumocephalus (which can result in headaches) and venous air embolism in rare cases. If air is chosen, the amount of air injected after loss-of-resistance should therefore be minimized. Evidence suggests that there is no difference in adverse outcome in the obstetric population when air or saline is used.[291] Another meta-analysis found that fluid inserted through the epidural needle before catheter insertion reduces the risk of epidural vein cannulation by the catheter.[287] One proposed disadvantage of using saline is that it may be more difficult to readily detect an accidental dural puncture.

An alternative method of identifying the epidural space is the hanging-drop technique. After the needle is placed into the ligamentum flavum, a drop of solution such as saline is placed within the hub of the needle. When the needle is advanced into the epidural space, the solution should be "sucked in." The theory behind this maneuver has traditionally been attributed to subatmospheric pressure in the epidural space, although recent experimental evidence in the cervical region suggests that using negative-pressure methods are poorly reliable and only useful in the sitting position.[292] The subatmospheric pressure has been related to expansion of the epidural space as the needle pushes the dura away from the ligamentum flavum.[293] The negative intrathoracic pressure may influence the pressure in the epidural space in the thoracic region and should be maximal during inspiration. Timing needle advancement to coincide with inspiration may be difficult, however.

When a lumbar midline approach is used, the depth from skin to the ligamentum flavum commonly reaches 4 cm, with the depth in most (80%) patients being between 3.5 and 6 cm; it can be longer or shorter in obese or very thin patients, respectively. Ultrasonography may be useful to predict the depth before needle insertion.[233] In the lumbar region, the ligamentum flavum is 5 to 6 mm thick in the midline. When a thoracic approach is chosen, needle control is of equal or greater importance because injury to the spinal cord is possible if the needle is advanced too far,

TABLE 45.7 Suggested Epidural Insertion Sites for Common Surgical Procedures

Nature of Surgery	Suggested Level of Insertion	Remarks
Hip surgery Lower extremity Obstetric analgesia	Lumbar L2-L5	
Colectomy, anterior resection Upper abdominal surgery	Lower thoracic T6-T8	Spread more cranial than caudal
Thoracic	T2-T6	Midpoint of surgical incision

Modified from Visser WA, Lee RA, Gielen MJ. Factors affecting the distribution of neural blockade by local anesthetics in epidural anesthesia and a comparison of lumbar versus thoracic epidural anesthesia. *Anesth Analg.* 2008;107:708–721.

although there are no data to suggest that approaching the epidural space at the lumbar level is any more or less safe than at the thoracic level. This may be partly because those using the thoracic technique are most often anesthesiologists with considerable experience in lumbar epidural anesthesia.[294] In addition, the increased angle of needle insertion in the thoracic region may theoretically provide an element of safety in that the more acute angle necessary to gain access to the epidural space provides some margin of safety (see Fig. 45.9).

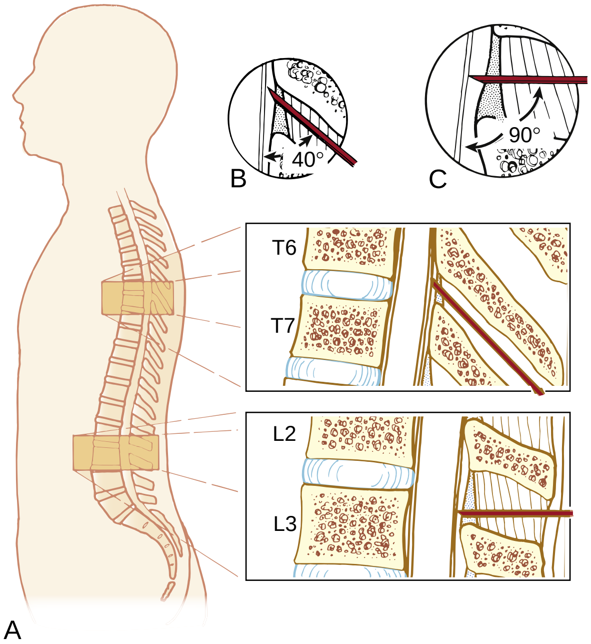

Fig. 45.9 (A) Lumbar and thoracic epidural technique. The increased angle of needle insertion during thoracic epidural cannulation may provide a slightly longer distance of "needle travel" before entering the subarachnoid space. In contrast to lumbar epidural cannulation (B), the distance traveled is modified by a more perpendicular angle of needle insertion (C).

When the epidural space is identified, the depth of the needle at the skin should be noted. The syringe can then be removed and a catheter gently threaded to approximately the 15- to 18-cm mark to ensure a sufficient length has entered the epidural space. The needle can then be carefully withdrawn, and the catheter is withdrawn to leave 4 to 6 cm in the space. Catheter space less than 4 cm in length in the epidural space may increase the risk of catheter dislodgement and inadequate analgesia, whereas threading more catheter may increase the likelihood of catheter malposition or complications.[295-298]

As described earlier, a false loss-of-resistance can occur and is one of the causes of a failed block. The Tsui test may be used to confirm the epidural catheter position.[299] This test stimulates the spinal nerve roots with a low electrical current conducted through normal saline in the epidural space and an electrically conducting catheter. A metal-containing catheter must be used, with the cathode lead of the nerve stimulator connected to the catheter via an electrode adapter, whereas the anode lead is connected to an electrode on the patient's skin. At currents of approximately 1 to 10 mA, corresponding muscle twitches (i.e., intercostal or abdominal wall muscles for thoracic epidural catheters) can be used to identify catheter tip location. Subarachnoid and subdurally positioned epidural catheters elicit motor responses at a much lower threshold current (<1 mA), because the stimulating catheter is in very close or direct contact with highly conductive CSF.[300,301]

When the catheter is positioned at the desired depth, it must be secured to the skin. Commercial fixation devices exist, and some are superior to tape alone.[302] Tunneling can reduce catheter migration and improve lasting block success.[303] However, tunneling has not been compared with noninvasive catheter fixation devices in a well-designed study.

Paramedian Approach

The paramedian approach is particularly useful in the mid- to high-thoracic region, where the angulation of the spine and the narrow spaces render the midline approach problematic. The needle should be inserted 1 to 2 cm lateral to the inferior tip of the spinous process corresponding to the vertebra above the desired interspace. The needle is then advanced horizontally until the lamina is reached and then redirected medially and cephalad to enter the epidural space. The Taylor approach is a modified paramedian approach via the L5-S1 interspace, which may be useful in trauma patients who cannot tolerate or are not able to maintain a sitting position. The needle is inserted 1 cm medial and 1 cm inferior to the posterior superior iliac spine and is angled medially and cephalad at a 45- to 55-degree angle.

Before initiating an epidural local anesthetic infusion, a test dose may be administered. The purpose of this is to exclude intrathecal or intravascular catheter placement. A small volume of lidocaine 1.5% with epinephrine is traditionally used for this purpose. A recent systematic review found reasonable evidence that 10 to 15 µg of epinephrine alone in nonpregnant adult patients was the best pharmacologic method of detecting intravascular placement, using endpoints of an increase in systolic blood pressure more than 15 mm Hg or an increase in heart rate more than 10 beats/min. The optimal method of detecting intrathecal or subdural placement, however, could not be ascertained.[304]

Combined Spinal-Epidural

CSE anesthesia was first described in 1937 but has subsequently been modified over the past 30 years[305-310] and the CSE technique is now seeing increasing popularity. A CSE allows flexibility in a number of clinical settings because the more rapid onset of spinal block compared with epidural anesthesia allows the operative procedure to begin earlier, whereas the epidural catheter still provides both effective postoperative analgesia and allows anesthesia to be extended as the spinal resolves. This is particularly useful during labor, where opioid and a small dose of local anesthetic may be injected through a small spinal needle to provide rapid analgesia, whereas the epidural catheter can be used thereafter for both analgesia and surgical anesthesia if an operative delivery becomes necessary. Another significant advantage of CSE in general is the ability to use a low dose of intrathecal local anesthetic, with the knowledge that the epidural catheter may be used to extend the block if necessary. The addition of either local anesthetic or saline alone to the epidural space via the catheter compresses the dural sac and increases the block height. This latter technique is called epidural volume extension (EVE) and has been shown in cesarean delivery to provide a comparable sensory block to larger doses of intrathecal local anesthetic (with no EVE) but with significantly faster motor recovery.[311] The principle of using a lower dose of spinal anesthetic and titrating the epidural dose after the spinal anesthetic to reach the appropriate block height is a reduction in side effects[312] with faster recovery, which can in turn potentially hasten discharge. This sequential technique also provides greater hemodynamic stability for high-risk patients using a lower initial mass of drug for spinal anesthetic, with subsequent gradual extension of the block if necessary using the epidural.

TECHNIQUE

The CSE technique most commonly involves placement of the epidural needle first, followed by either a "needle through needle" technique to reach the subarachnoid space or an altogether separate spinal needle insertion at either the same or different interspace. Some but not all studies have demonstrated greater success and lower failure rates with the separate needle insertion technique.[313-316] This method has the potential advantage of being able to confirm that the epidural catheter is functional before spinal anesthesia is administered, which, although it is time consuming, may be advantageous if the epidural catheter is to be relied upon for anesthesia when the spinal component resolves. Conversely, this method theoretically risks shearing the epidural catheter that is already in situ. If a needle-through-needle technique is chosen, special CSE kits are available with long spinal needles, some of which can be locked in place for the subarachnoid injection.

Caudal Anesthesia

Caudal anesthesia is popular in pediatric anesthesia (see Chapter 77), but the technique also can be used in adults, although it is unpredictable when upper abdominal or thoracic spread is required. Its indications in adults therefore are essentially the same as those for lumbar epidural anesthesia, although it may be particularly useful when sacral anesthetic spread is desired (e.g., perineal, anal, rectal procedures), where a spinal surgery scar may prevent a lumbar anesthetic technique and, more commonly, in chronic pain and cancer pain management (see Chapter 51). The use of fluoroscopic guidance and, more recently, ultrasonography can help guide correct needle placement and reduce the rate of a failed block.[317] Ultrasonography is of even greater benefit in children because the lack of bony ossification allows visualization of both local anesthetic spread and the position of caudal epidural catheters.[318,319]

PHARMACOLOGY

The local anesthetics used are similar to those described for epidural anesthesia and analgesia. However, in adults approximately twice the lumbar epidural dose is required to achieve a similar block with the caudal approach. The spread is also variable, making this technique in adults unreliable for procedures above the umbilicus.

TECHNIQUE

Patient preparation as described before for spinal and epidural anesthesia must be equally applied to caudal anesthesia, namely consent, monitoring and resuscitation equipment, intravenous access, and the same asepsis precautions. Caudal anesthesia requires identification of the sacral hiatus. The sacrococcygeal ligament (i.e., extension of ligamentum flavum) overlies the sacral hiatus between the two sacral cornua. To facilitate locating the cornua, the posterior superior iliac spines should be located and, by using the line between them as one side of an equilateral triangle, the location of the sacral hiatus should be approximated (Fig. 45.10). Ultrasonography can also be used to identify these landmarks,[317-319] as can fluoroscopy. Three positions (see Chapter 34) are available for caudal anesthesia, with the prone position most often chosen in adults, the lateral decubitus position most chosen in children, and the knee-chest position the most infrequently used. The lateral decubitus position is used in children because it is easier to maintain a patent airway in this position than in the prone position, and the landmarks are more easily palpable than they are in adults (see Chapter 76). This consideration is valuable because caudal anesthesia is often combined with general anesthesia in pediatric patients to decrease the amount of volatile agent used intraoperatively or to provide postoperative analgesia. In contrast, a caudal block is often administered during preoperative sedation in adults and when the prone position is applicable. When placing a patient in the prone position, a pillow should be inserted beneath the iliac crests to rotate the pelvis and make cannulation of the caudal canal easier. An additional aid is to spread the lower extremities about 20 degrees with the heels rotated laterally, which minimizes gluteal muscle contraction and eases needle insertion.

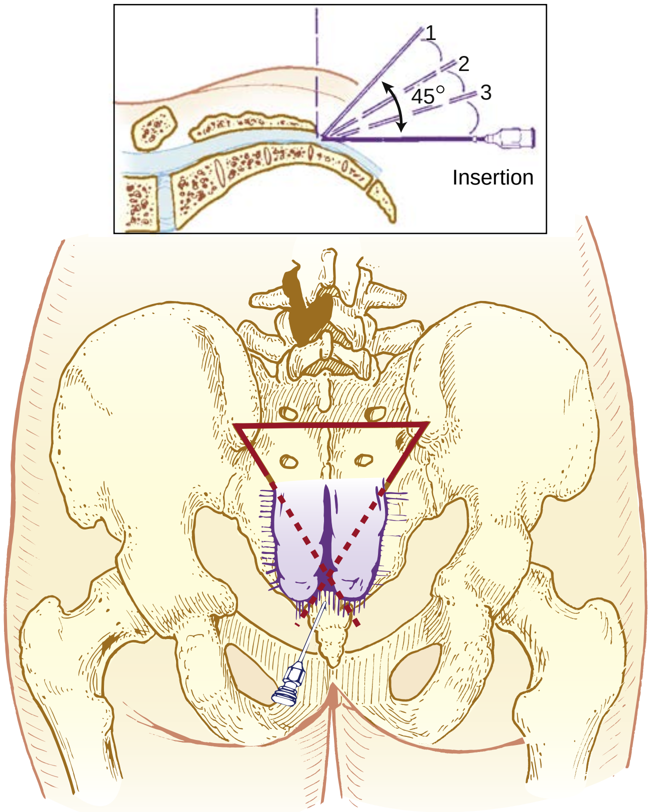

Fig. 45.10 Caudal technique. Palpating fingers locate the sacral cornua by using the equilateral triangle. Needle insertion is completed by insertion and withdrawal in a stepwise fashion (*inset,* so-called 1-2-3 insertion) until the needle can be advanced into the caudal canal and the solution can be injected easily (without creation of a subcutaneous "lump" of fluid).

After the sacral hiatus is identified, the index and middle fingers of the palpating hand are placed on the sacral cornua, and after local infiltration, the caudal needle (or Tuohy needle if a catheter is to be placed) is inserted at an angle of approximately 45 degrees to the sacrum. While the needle is advanced, a decrease in resistance to needle insertion should be appreciated as the needle enters the caudal canal. The needle is advanced until bone (i.e., the dorsal aspect of the ventral plate of the sacrum) is contacted and then is slightly withdrawn, and the needle is redirected so that the angle of insertion relative to the skin surface is decreased. In male patients, this angle is almost parallel to the coronal plane; in female patients, a slightly steeper angle (15 degrees) is necessary. During redirection of the needle, loss-of-resistance is sought to confirm entry into the epidural space, and the needle advanced no more than approximately 1 to 2 cm into the caudal canal. In adults, the tip should never be advanced beyond the S2 level (approximately 1 cm inferior to the posterior superior iliac spine), which is the level to which the dural sac extends. Additional advancement of the needle increases the risk of dural puncture, and unintentional intravascular cannulation becomes more likely. One method of increasing the likelihood of correct caudal needle placement is to inject 5 mL of saline rapidly through the caudal needle while palpating the skin overlying the sacrum. If no midline bulge is detected, the needle is probably positioned correctly. In contrast, if a midline bulge is detected during saline injection, the needle is positioned incorrectly.

After ensuring correct needle position and before injection of the therapeutic dose of caudal anesthetic, aspiration should be performed and a test dose administered because, as in lumbar epidural anesthesia, a vein or the subarachnoid space can be entered unintentionally.

Complications

The physiologic effects of neuraxial blocks may be misinterpreted as complications; however, clear distinction should be made between the physiologic effects of the neuraxial technique and complications, which imply some harm to the patient.[320] The material risks associated with neuraxial anesthesia must be intimately understood and respected because catastrophic injury is not unknown and serves to remind us that a person's nervous system is at the other end of the needle.[321]

NEUROLOGIC

Serious neurologic complications associated with neuraxial anesthesia are rare. As such, prohibitively large numbers of patients are required for study to estimate the frequency of these events. The true incidence of most neurologic injury after neuraxial anesthesia is unknown with published accounts of neurologic complications invariably influenced by the differing identification and reporting processes. The ASRA comprehensively addresses this important topic in their updated Practice Advisory on Neurologic Complications.[76]

Paraplegia

The frequency of paraplegia related to neuraxial anesthesia is reported to be approximately 0.1/10,000,[322,323] and the mechanism of such a severe injury is likely multifactorial and difficult to identify for certain.[324] Although injury resulting from direct needle trauma to the spinal cord[325-329] may be self-evident, historical cases highlight the fundamental danger that accompanies the injection of a foreign substance into the CSF. The highly publicized cases of Woolley and Roe, two healthy, middle-aged men who became paraplegic after spinal anesthesia by the same anesthesiologist using the same drug on the same day for minor surgery at the same hospital in the United Kingdom in 1947, arguably set back the practice of spinal anesthesia for decades despite evidence that contamination by the descaling liquid used to cleanse the procedure tray had most likely been responsible.[4] Another example of catastrophic injury related to intrathecal injectate was the chloroprocaine neurotoxicity experience in the early 1980s, during which several patients developed adhesive arachnoiditis, cauda equina syndrome, or permanent paresis thought to be related to a combination of low pH and the antioxidant sodium bisulfite preservative used in early (and discontinued) preparations of the short-acting ester local anesthetic chloroprocaine.[136-139,330]

Profound hypotension or ischemia of the spinal cord can be important contributing factors in cases of paraplegia associated with neuraxial anesthesia. Anterior spinal artery syndrome, characterized by painless loss of motor and sensory function, is associated with anterior cord ischemia or infarction with sparing of proprioception, which is carried by the posterior column. The anterior cord is believed to be especially vulnerable to ischemic insult because of its single and tenuous source of arterial blood supply (the artery of Adamkiewicz). Ischemia caused by any one or a combination of profound hypotension, mechanical obstruction, vasculopathy, or hemorrhage can contribute to irreversible anterior cord damage.[331-333]

Cauda Equina Syndrome

The rate of cauda equina syndrome is approximately 0.1/10,000 and invariably results in permanent neurologic deficit.[322] The lumbosacral roots of the spinal cord may be particularly vulnerable to direct exposure to large doses of local anesthetic, whether it is administered as a single injection of relatively highly concentrated local anesthetic (e.g., 5% lidocaine)[334] or prolonged exposure to a local anesthetic through a continuous catheter.[5,335,336] The US Food and Drug Administration withdrew approval for spinal catheters smaller than 24-g in size in 1992 because of concerns about a perceived association between the small-bore catheters and the development of cauda equina syndrome.[337] Although small-bore catheters can reduce the risk of headache, they can predispose to pooling of local anesthetic around the lumbosacral nerve roots, possibly because of slow injectate flow through the fine-bore catheter, thereby exposing them to high concentrations of local anesthetic. However, small-bore spinal catheters are being used effectively in Europe, and they are beginning to reappear in the United States, although it has taken nearly 15 years for them to emerge from the regulatory cloud of the early 1990s.[338] Another risk factor for cauda equine syndrome may be spinal stenosis wherein local anesthetic distribution may be limited, thus exposing the cauda equine to higher concentrations of local anesthetic.

Epidural Hematoma

Bleeding within the vertebral canal can cause ischemic compression of the spinal cord and lead to permanent neurologic deficit if not recognized and evacuated expeditiously. Many risk factors have been associated with the development of an epidural hematoma, including difficult or traumatic needle or catheter insertion,[339] coagulopathy, elderly age, and female gender.[340] Radicular back pain, prolonged blockade longer than the expected duration of the neuraxial technique, and bladder or bowel dysfunction are features commonly associated with a space-occupying lesion within the vertebral canal and should prompt magnetic resonance imaging on an urgent basis. Before the recently published United Kingdom National Health Service (NHS) audit, the largest contemporary studies reported rates of epidural hematoma of less than 0.06/10,000 after spinal anesthesia, whereas the reported rates of epidural hematoma after epidural blockade in the audit were as much as 10-fold higher.[294,341-345] The United Kingdom NHS audit arguably provides the most accurate rates of neurologic complications associated with neuraxial anesthesia in contemporary practice. This unique prospective nationwide audit found five cases of epidural hematoma among 707,455 neuraxial techniques (0.07/10,000), all of which occurred among 97,925 perioperative epidural techniques (0.5/10,000) performed over the course of 1 year.[323]

Nerve Injury

In 1955, Vandam and Dripps[346] were the first to capture data prospectively on nerve injury from more than 10,000 patients who underwent spinal anesthesia. No severe neurologic injuries occurred in this population. In 1969, Dawkins[347] published the classic review of neurologic complications after 32,718 epidural anesthetics and reported the frequency of transient and permanent nerve injury to be 0.1% and 0.02%, respectively. Despite interim advances in practice and research methodology, some of the largest contemporary studies available[341,344,348-350] suggest that the rate of neurologic injury related to neuraxial anesthesia is mostly unchanged compared with that reported nearly a half century ago. Most notable from these contemporary data are that epidural (including CSE) anesthesia is likely associated with a more frequent rate of radiculopathy or peripheral neuropathy compared with spinal anesthesia,[322] and that neuraxial anesthesia performed in adults for the purposes of perioperative anesthesia or analgesia is apparently associated with a higher likelihood of neurologic complications compared with that performed in the obstetric, pediatric, and chronic pain settings.[323,341,342,351,352] The rate of permanent nerve injury after neuraxial blockade is even more difficult to determine because methods of investigation and diagnosis, determination of causation, and reporting of outcomes are highly variable within the literature.[353] The United Kingdom NHS audit found the overall rate of permanent nerve injury to be 7 in 707,455 or 0.1/10,000,[323] which is remarkably similar to studies published a half century earlier by Dawkins. Three cases of nerve injury occurred among 293,050 epidurals (0.1/10,000), 3 among 324,950 spinal anesthetics (0.1/10,000), and 1 among 41,875 CSEs (0.2/10,000), mostly in young, healthy patients. Procedure-related risk factors traditionally associated with nerve injury after neuraxial anesthesia in the perioperative setting include radicular pain or paresthesia occurring during the procedure.[321,344,354,355]

Arachnoiditis

Arachnoiditis, an inflammatory reaction of the meninges, is rare after neuraxial anesthesia and its true incidence is unknown. The potential contributory effects of chlorhexidine disinfectant solution has led to the recommendation that chlorhexidine must dry fully before needle puncture,[76] and measures must also be taken to avoid splashing of any chlorhexidine solution onto the needles or syringes, and especially contamination of the injectate drugs.

Post–Dural Puncture Headache

A relatively common complication of neuraxial anesthesia is post–dural puncture headache. As the name implies, post–dural puncture headache is believed to result from unintentional or intentional puncture of the dura membrane in the setting of neuraxial anesthesia or after myelography and diagnostic lumbar puncture. There are two possible explanations for the cause of the headache, neither of which has ever been proven. First, the loss of CSF through the dura is proposed to cause traction on pain-sensitive intracranial structures as the brain loses support and sags. Alternatively, the loss of CSF initiates compensatory yet painful intracerebral vasodilation to offset the reduction in intracranial pressure.[356] The characteristic feature of a post–dural puncture headache is a frontal or occipital headache that worsens with the upright or seated posture and is relieved by lying supine. Associated symptoms can include nausea, vomiting, neck pain, dizziness, tinnitus, diplopia, hearing loss, cortical blindness, cranial nerve palsies, and even seizures. In more than 90% of cases, the onset of characteristic post–dural puncture headache symptoms will begin within 3 days of the procedure,[357] and 66% start within the first 48 hours.[358] Spontaneous resolution usually occurs within 7 days in the majority (72%) of cases, whereas 87% of cases resolve by 6 months.[359]

Post–dural puncture headache can occur in the setting of either spinal or epidural anesthesia, the former associated with certain modifiable risk factors during intentional dural puncture and the latter associated with unintentional puncture of the dura by advancing the Tuohy needle. Orienting a needle bevel parallel with the axis of the spine, such that the longitudinal fibers of the dura would more likely be separated than cut, results in a lower incidence of postspinal puncture headache.[360] This clinical observation is supported by laboratory investigations[361] showing that simulated spinal puncture with cone-shaped (pencil-point) spinal needle tips produces slower transdural loss of fluid than a similar puncture with cutting-tipped needles. Indeed meta-analysis has confirmed that noncutting needle tip designs have a lower frequency of post–dural puncture headache than do cutting spinal needle tip designs.[362] Other studies suggest that the collagen layers of the dura are oriented in a multidirectional fashion, not always in a cephalocaudad direction, and are variable in thickness, leading to the suggestion that damage to the longitudinal cells of the arachnoid membrane is more likely to be influenced by the type of bevel and may even be the predominant factor affecting post–dural puncture headache.[9] Reports vary as to whether the incidence of post–dural puncture headache is increased with the CSE technique compared with epidural alone.[363,364]

Aside from the type of needle tip (cutting vs. pencil-point) and the bevel direction, there are additional risk factors common to the performance of both spinal and epidural anesthesia that contribute to the likelihood of developing a post–dural puncture headache. These risk factors are listed in Box 45.2.[365]

Conservative management for post–dural puncture headache includes supine positioning, hydration, caffeine, and oral analgesics. Sumatriptan has also been used with varying effect but is not without side effects.[366,367] Epidural blood patch is the definitive therapy for post–dural puncture headache.[368] This therapy was introduced by Gormley[369]; its safety and efficacy have been well documented, and contemporary practice has validated that a single epidural blood patch continues to have up to a 90% initial improvement rate[370] and persistent resolution of symptoms in 61% to 75% of cases.[371]

Epidural blood patch is ideally performed 24 hours after dural puncture and after the development of classic

BOX 45.2 Relationships Among Variables and Post–Spinal Puncture Headache

Factors That Can Increase the Incidence of Headache After Spinal Puncture

- Age: Younger, more frequent
- Sex: Females > males
- Needle size: Larger > smaller
- Needle bevel: Less when the needle bevel is placed in the long axis of the neuraxis
- Pregnancy: More when pregnant
- Dural punctures: More with multiple punctures

Factors That Do Not Increase the Incidence of Headache After Spinal Puncture

- Insertion and use of catheters for continuous spinal anesthesia
- Timing of ambulation

post–dural puncture headache symptoms. The efficacy of prophylactic epidural blood patching is not supported by evidence.[372,373] By injecting radionuclide-labeled red blood cells epidurally, Szeinfeld and co-workers[374] demonstrated that approximately 15 mL of blood will spread over a mean distance of nine spinal segments, and that the direction of spread was preferentially cephalad relative to the level of blood injection. As a result, these authors recommend inserting the blood patch needle at or caudad to the level of the previous culprit dural puncture. These findings have since been validated by magnetic resonance imaging of epidural blood patch spread.[375] One multinational, multicenter, randomized, blinded trial suggested that 20 mL of blood is a reasonable starting target volume.[376] A second epidural blood patch may be performed 24 to 48 hours after the first in the case of ineffective or incomplete relief of symptoms.

Transient Neurologic Symptoms

Traditionally associated with lidocaine, TNS have been described after intrathecal administration of every local anesthetic used for spinal anesthesia. TNS, previously known as transient radicular irritation,[377] are usually characterized by bilateral or unilateral pain in the buttocks radiating to the legs or, less commonly, isolated buttock or leg pain. Symptoms occur within 24 hours of the resolution of an otherwise uneventful spinal anesthetic and are not associated with any neurologic deficits or laboratory abnormalities.[378] The pain can range from mild to severe and typically resolves spontaneously in 1 week or less.[379] The likelihood of TNS are highest after intrathecal lidocaine and mepivacaine, and are far less frequent with bupivacaine and other local anesthetics.[147,159,380] The phenomenon is not related to the concentration of lidocaine,[147] the addition of dextrose or epinephrine, or solution osmolarity. The type of needle can influence the likelihood of TNS, with the rate reduced by a double-orifice needle,[381] possibly because single-orifice needles increase the risk of injecting anesthetic caudally in the thecal sac. TNS are not commonly associated with epidural procedures but have occurred with epidural lidocaine and other local anesthetics.[253,382] Finally, TNS occur more commonly in patients who are placed in the lithotomy position for surgery. Nonsteroidal antiinflammatory drugs are the first line of treatment, but pain can be severe and may even require opioids.

CARDIOVASCULAR

Hypotension

Hypotension may be considered a complication of neuraxial blockade if the patient faces harm. Recent guidance has placed more emphasis on avoiding hypotension during neuraxial anesthesia (defined as 20%–30% below baseline) in order to reduce the possibility of spinal cord ischemia or infarction.[76] In the setting of spinal anesthesia, hypotension (defined as systolic blood pressure <90 mm Hg) is more likely to occur with a variety of factors including peak block height greater than or equal to T5, age older than or equal to 40 years, baseline systolic blood pressure less than 120 mm Hg, combined spinal and general anesthesia, spinal puncture at or above the L2-L3 interspace, and the addition of phenylephrine to the local anesthetic.[51] Hypotension (defined as a reduction in mean arterial blood pressure >30%) is independently associated with chronic alcohol consumption, history of hypertension, BMI, and the urgency of surgery.[383] Nausea is a common symptom of hypotension in the setting of neuraxial anesthesia, as are vomiting, dizziness, and dyspnea. Although prevention of hypotension caused by vasodilatation using a prophylactic ("preloading") infusion of colloid or crystalloid during the performance of the neuraxial block ("coloading") has been reported,[384] this is no longer recommended as a routine practice.[384]

Bradycardia

The development of severe bradycardia after spinal anesthesia has long been recognized as an important risk of spinal anesthesia.[385,386] Bradycardia stems from blockade of the thoracic sympathetic fibers (preganglionic cardiac accelerator fibers originating at T1-T5), as well as reflexive slowing of the heart rate as vasodilation reduces the venous return to the right atrium where stretch receptors respond by a compensatory slowing of the heart rate. Factors that may increase the likelihood of exaggerated bradycardia (40–50 beats/min) include baseline heart rate less than 60 beats/min, age younger than 37 years, male gender, nonemergency status, β-adrenergic blockade, and prolonged case duration. Severe bradycardia (<40 beats/min) is associated with a baseline heart rate less than 60 beats/min and male gender.[387]

Cardiac Arrest (also see Chapter 87)

In a review of closed insurance claims, Caplan and associates[388] identified 14 cases of sudden cardiac arrest in healthy patients receiving spinal anesthesia. The etiology of sudden cardiac arrest after spinal anesthesia is not understood. Whether these catastrophic events represented lack of vigilant monitoring and treatment as opposed to some mysterious physiologic explanation is not known.[389] The latter notwithstanding, it is clear that hypoxemia and oversedation are complicit in the severe bradycardia and asystole that can occur suddenly during well-conducted spinal anesthesia.[390,391] Curiously, these rare events seem to be preferentially associated with spinal anesthesia rather than epidural techniques. In their inaugural survey of French anesthesiologists, Auroy and colleagues reported the rate of cardiac arrest to be 6.4/10,000 after spinal anesthesia compared with 1/10,000 for all other neuraxial and peripheral regional anesthesia techniques combined.[344] In their larger follow-up survey of all anesthesiologists in France, Auroy and colleagues[350] reported 10 cases of cardiac arrest after 35,439 spinal anesthetics (2.5/10,000) and none after 5561 epidural techniques. Most recently, Cook and colleagues uncovered three cases of cardiovascular collapse among 707,425 neuraxial blocks (0.04/10,000) during their nationwide audit, two of which were during spinal anesthesia and one in the setting of CSE.[323]

RESPIRATORY

Neuraxial opioids are commonly added to local anesthetic solutions to improve the quality and duration of neuraxial anesthesia and analgesia. The risk of respiratory depression associated with neuraxial opioids is dose dependent, with a reported frequency that approaches 3% after the administration of 0.8 mg of intrathecal morphine.[392] Respiratory depression may stem from rostral spread of opioids within the CSF to the chemosensitive respiratory centers in the brainstem.[65] With lipophilic anesthetics, respiratory depression is generally an early phenomenon occurring within the first 30 minutes; respiratory depression has never been described more than 2 hours after the administration of intrathecal fentanyl or sufentanil.[225] With intrathecal morphine, there is a risk of late respiratory depression, occurring as much as 24 hours after injection. Respiratory monitoring for the first 24 hours after the administration of intrathecal morphine is therefore advisable. Patients with sleep apnea can be especially sensitive to the potent respiratory-depressant effects of opioid medications and although definitive safety data evidence is lacking, the decision to administer neuraxial opioids to these patients is made with considerable caution.[393,394] Older patients also have a higher risk of respiratory depression, and the dose of neuraxial opioids should be reduced in this population (see Chapter 65). Coadministration of systemic sedatives also increases this risk.

INFECTION

Bacterial meningitis and epidural abscess are rare, but potentially catastrophic, infectious complications of all neuraxial techniques. Sources of infection in neuraxial procedures include the equipment, the patient, or the practitioner. Staphylococcal infections arising from the patient's skin are one of the most common epidural-related infections, whereas oral bacteria such as *Streptococcus viridans* are a common cause of infection after spinal anesthesia, underscoring the need for the clinician to wear a facemask when performing neuraxial procedures. Other factors that may increase the likelihood of infection include the presence of a concomitant systemic infection, diabetes, immunocompromised states,[90] and prolonged maintenance of an epidural (or spinal) catheter. Large contemporary studies estimate the rate of serious neuraxial infection to be less than 0.3/10,000[341,348,350] for spinal anesthesia, whereas infectious complications after epidural techniques may be at least twice as common.[341,348,350,395-397] Obstetric patients are less likely to develop deep infections related to epidural analgesia. The recent United Kingdom NHS audit reported no cases of meningitis and eight cases of epidural abscess after 707,455 neuraxial techniques, five of which occurred among 293,050 epidural techniques, two among 324,950 spinal anesthetics, and one among 47,550 caudal blocks.[323]

In 2017, the ASA and ASRA published a practice advisory regarding infectious complications associated with neuraxial anesthesia,[229] specifically addressing (1) prevention, (2) diagnosis, and (3) management. Previous publications have addressed infectious risks of neuraxial anesthesia in the febrile or infected patient,[90] the immunocompromised patient,[398] and in the setting of chronic pain treatments.[399]

Aseptic meningitis occurred mostly in the early 20th century, likely secondary to chemical contamination and detergents, which are no longer present in modern preservative-free preparations.

BACKACHE

Back injury is perhaps the most feared complication of neuraxial anesthesia among patients. Evidence indicates that the incidence of back pain after spinal anesthesia is not different from general anesthesia.[400] Indeed, up to 25% of all surgical patients undergoing anesthesia, regardless of anesthetic technique, experience backache, the incidence of which increases to 50% when surgery lasts 4 to 5 hours.[401] There is also no association between epidural analgesia and new-onset back pain up to 6 months postpartum.[402,403] Preexisting back pain does appear to be a risk factor for persistent back pain after neuraxial anesthesia, although the severity of the pain does not appear to be worsened. Other risk factors include immobilization during surgery greater than 2.5 hours, lithotomy position, BMI greater than 32 kg/m^2, and multiple attempts at block placement.[400]

NAUSEA AND VOMITING

There are multiple possible mechanisms that contribute to nausea and vomiting in the setting of neuraxial anesthesia, including direct exposure of the chemoreceptive trigger zone in the brain to emetogenic drugs (e.g., opioids), as well as hypotension associated with generalized vasodilation and gastrointestinal hyperperistalsis secondary to unopposed parasympathetic activity (see also Chapter 80).[404] Although regional anesthesia is often recommended as an alternative to general anesthesia for patients at risk for postoperative nausea and vomiting, there are few studies that have primarily investigated the effects of neuraxial anesthesia on postoperative nausea and vomiting with sufficient statistical power. Factors associated with developing nausea or vomiting after spinal anesthesia include the addition of phenylephrine or epinephrine to the local anesthetic, peak block height greater than or equal to T5, baseline heart rate greater than 60 beats/min, use of procaine, history of motion sickness, and the development of hypotension during spinal anesthesia. Among the opioids commonly added to intrathecal or epidural local anesthetics, morphine administration has the most frequent risk of nausea or vomiting, whereas fentanyl and sufentanil carry the least frequent risk.[404] Neuraxial opioid-related nausea and vomiting appears to be dose dependent. Using less than 0.1 mg morphine reduces the risk of nausea and vomiting, without compromising the analgesic effect.[225]

URINARY RETENTION

Urinary retention can occur in as much as one third of patients after neuraxial anesthesia. Local anesthetic blockade of the S2, S3, and S4 nerve roots inhibits urinary function as the detrusor muscle is weakened. Neuraxial opioids can further complicate urinary function by suppressing detrusor contractility and reducing the sensation of urge.[405] Spontaneous return of normal bladder function is expected once the sensory level decreases to below S2-3.[406] Although male gender and age have been (albeit inconsistently) linked to urinary retention after neuraxial anesthesia, the administration of intrathecal morphine is strongly associated with this complication.[405,407,408]

PRURITUS

Pruritus can be distressing to the patient. It is the most common side effect related to the intrathecal administration of opioids, with rates between 30% and 100%.[225] Pruritus actually occurs more commonly after intrathecal opioid administration than after intravenous opioid administration and is not dependent on the type or dose of opioid administered. Reducing the dose of intrathecal sufentanil from 5 μg to as little as 1.5 μg can reduce the likelihood of pruritus without compromising analgesia when added to hyperbaric bupivacaine for cesarean delivery (see Chapter 62).[409] The mechanism of pruritus is unclear but is likely related to the central opioid receptor activation rather than histamine release because naloxone, naltrexone, or the partial agonist nalbuphine can be used for treatment. Ondansetron and propofol are also useful therapies. Some antiinflammatories have been shown to reduce pruritus (e.g., diclofenac and tenoxicam), while mirtazapine, an antidepressant with $5HT_3$ antagonism properties like ondansetron, may also be helpful if administered preoperatively.

SHIVERING

The rate of shivering related to neuraxial anesthesia is as frequent as 55%.[410] The intensity of shivering is likely related more to epidural anesthesia than spinal.[411] Although there are multiple possible explanations for the difference in shivering intensity, this observation may simply be related to the inability to shiver because of the profound motor block associated with spinal anesthesia compared with epidural techniques. Another explanation may be the relatively cold temperature of the epidural injectate, which can affect the thermosensitive basal sinuses.[410] The addition of neuraxial opioids, specifically fentanyl and meperidine, reduces the likelihood of shivering.[410] Recommended strategies to prevent shivering after neuraxial anesthesia include prewarming the patient with a forced air warmer for at least 15 minutes and avoiding the administration of cold epidural and intravenous fluids.

WRONG ROUTE ADMINISTRATION

Wrong route administration refers to the infusion or injection of a drug into the wrong body compartment. In addition to epidural catheter migration or inadvertent intravascular placement (described below), an epidural infusion may be mistakenly connected to an intravascular device. Using less cardiotoxic local anesthetics may reduce the risk of harm if this does occur. Prevention is paramount and devices have been developed to make regional anesthesia and intravenous connections technically incompatible.

COMPLICATIONS UNIQUE TO EPIDURAL ANESTHESIA

Intravascular Injection

Epidural anesthesia can produce local anesthetic–induced systemic toxicity (see Chapter 29), primarily through the unintentional administration of drug into an epidural vein. The frequency of vascular puncture with the needle or cannulation with the catheter can reportedly approach 10%, with the highest rates seen in the obstetric population, where these vessels are relatively dilated and more vulnerable to entry.[287,412] The rate of seizures related to epidural anesthesia may be as frequent as 1%.[294,344,350] In obstetrics (see also Chapter 62), the likelihood of intravascular injection is decreased by placing the patient in the lateral (as opposed to the sitting) position during needle and catheter insertion, administering fluid through the epidural needle before catheter insertion, using a single-orifice type rather than a multiorifice catheter or a wire-embedded polyurethane type compared with polyamide epidural catheter, and advancing the catheter less than 6 cm into the epidural space. The paramedian as opposed to the midline needle approach, and the use of a smaller-gauge epidural needle or catheter, does not reduce the risk of epidural vein cannulation.[287]

One of the most controversial issues related to epidural anesthesia has been the use of an epinephrine-containing test dose.[413] Epinephrine (15 μg) in 3 mL of local anesthetic remains the best pharmacologic method of detecting intravascular placement in nonpregnant adult patients.[304] However, controversy surrounds the use of epinephrine in obstetric patients, in whom uterine blood flow may be decreased by the intravascular injection, thereby putting the fetus at risk, and where the cardiovascular changes occurring in active labor may represent a false-positive response to epinephrine. Although epinephrine may place the fetus at risk in theory,[414] no such case has been described. The epidural epinephrine test dose can be unreliable in patients receiving β-adrenergic blockers[415] or if the test dose is administered during general anesthesia.[416] Because there is no fail-safe method of guaranteeing an extravascular location of an epidural local anesthetic, prevention of systemic toxicity should also involve aspiration of the catheter and incremental administration of the local anesthetic. The onset of block, quality of the block, and block height are unaffected by administration of the epidural drug in 5-mL fractions.[417]

Subdural Injection

Blomberg[418] used a fiberoptic technique to demonstrate that the subdural extra-arachnoid space is easily entered in 66% of autopsy attempts in humans. Despite this being an infrequent clinical problem with epidural anesthesia (<1%), it does allow a visual understanding of the subdural complications of epidural anesthesia.[419] This space, unlike the epidural space, also extends intracranially. When an epidural block is performed and a higher-than-expected block develops, but only after a delay of 15 to 30 minutes (unlike a total spinal), subdural placement of local anesthetic must be considered. With a subdural block, the motor block will be modest compared to the extent of the sensory block, and the sympathetic block may be exaggerated. The treatment is symptomatic.

COMPLICATIONS UNIQUE TO COMBINED SPINAL-EPIDURALS

The risk of metal toxicity from abraded spinal needle particles using the needle-through-needle technique has not been confirmed.[420]

Outcomes

Although the benefit of properly applied epidural anesthesia and analgesia as an excellent pain relief modality is unquestionable, its effect on postoperative morbidity and mortality is becoming more clear. Early meta-analysis showed a relative risk reduction in overall mortality in patients receiving neuraxial blockade, by as much as 30% in patients undergoing all types of surgery,[421] but these results included studies now over 40 years old, which may not reflect contemporary anesthetic practice. Recent work has focused on large prospective and retrospective database analyses as well as randomized controlled trials with some analyses including over 1 million patients.[422] Although these too must be treated with caution, there still appear to be benefits of neuraxial anesthesia beyond superior analgesia, particularly when neuraxial is used instead of, rather than combined with, general anesthesia.[422a] Furthermore, the specific surgical procedure may also influence outcome and it may be that any benefit is both procedure specific and technique specific (i.e., thoracic epidural may be more advantageous than lumbar epidural, and epidural local anesthetic may be more advantageous than epidural opioid).

As general anesthesia has become safer over the decades, demonstrating a mortality benefit is more challenging. Some large retrospective studies do show a reduction in mortality, but when present, the absolute difference is small. For cardiac surgery, meta-analyses have shown a reduced risk of mortality and myocardial infarction (composite endpoint); a reduced risk for acute renal failure, pulmonary complications, and supraventricular arrhythmia; and reduced duration of postoperative controlled ventilation in patients who received combined intraoperative general anesthesia and TEA.[74,423] For major thoracic and abdominal surgery, thoracic epidural analgesia can reduce mortality, along with reductions in respiratory complications and opioid consumption, and improvements in cough and time to ambulation.[422,424,425] Conversely, there is now some evidence that myocardial infarction rates may be increased when epidural and general anesthesia are combined.[422]

Mortality and morbidity aside, there are other important advantages of neuraxial blockade. For bilateral total knee arthroplasty, neuraxial anesthesia decreases the rate of blood transfusion.[426] In patients undergoing major vascular and abdominal surgery, thoracic epidural local anesthetic infusion can reverse postoperative paralytic ileus associated with pain-induced sympathetic overactivity and systemic opioid.[427] Lumbar epidural infusion or thoracic epidural opioid infusion alone does not speed intestinal function recovery. For fast-track laparoscopic colon resection, thoracic epidural analgesia provides superior pain relief but fails to speed intestinal function recovery or hospital discharge time. In a recent meta-analysis, which compared neuraxial to general anesthesia for all major limb and truncal surgery combined, there was a reduction in length of stay in hospital, but this was measured in hours rather than days.[422]

What are the potential effects of neuraxial anesthesia on stress response, the immune system, and cancer recurrence?[428-430a] Functional cell-mediated immunity is required for monitoring and eradicating cancer cell growth. Lymphocytes, such as the natural killer (NK) cells and the cytotoxic T lymphocytes, can lyse the cancer cell through the perforin and granzyme pathway or through secretion of cytokines (e.g., interferons) to induce cancer cell apoptosis. In addition, the helper T cells control tumor angiogenesis through interferons, inhibit oncogenic signaling, and stimulate tumor destruction by engaging macrophages and granulocytes through interleukin production. There is an inverse relationship between NK cell activity at the time of surgery and the development of metastatic disease. Systemic cancer cell seeding happens during surgical dissection and manipulation. Unfortunately, this happens at a time of significant immunosuppression. Surgically induced stress hormone (e.g., corticosteroids), as well as inhaled volatile anesthetics and systemic opioids (morphine and fentanyl), can diminish NK cell function. Morphine also has proangiogenic properties that may promote dissemination of angiogenesis-dependent tumors. TEA and analgesia may be beneficial by virtue of its opioid and general anesthetic sparing and surgical stress–alleviating properties. Some encouraging data indicate a reduction of cancer recurrence associated with the use of perioperative epidural anesthesia and analgesia in patients undergoing retropubic prostatectomy,[431,432] rectal cancer,[433] and ovarian cancer resection.[434,435] Volatile, but not intravenous, anesthetics have also been shown to have a negative effect on immune function and cancer spread and therefore any benefit of regional anesthesia may simply be due to a reduction or avoidance in the use of volatile anesthetic drugs. In the same manner, this potential effect on the immune system may explain why surgical site infection has been shown to be reduced when using neuraxial compared general anesthesia in some, but not all, studies.[422]

Recent Advances

ULTRASOUND

There is now considerable evidence to support the role of ultrasound imaging for neuraxial blockade, and for lumbar techniques in particular.[436] Ultrasound can accurately identify the intervertebral levels, the midline spinous process, the midline interspinous window, and the paramedian interlaminar window (see also Chapter 46).[233] Bone does not permit ultrasound beam transmission, thus casting a hypoechoic (dark) shadow on the image. Conversely, passage of the ultrasound beam through the interspinous and interlaminar windows allows visualization of the hyperechoic dura (a bright line), the subarachnoid space, and the posterior aspect of the vertebral body. Visualization of the ligamentum flavum and epidural space is often more difficult. Successful transverse or longitudinal scan facilitates identification of the optimal location for proper needle insertion during neuraxial block and an estimation of the skin-to-dura distance. This is particularly useful in patients with difficult surface anatomic landmarks (e.g., obesity), spine pathology (e.g., scoliosis), and previous spine surgery (e.g., laminectomy).[437]

Ultrasound-facilitated neuraxial block involves preprocedure scanning of the spine to determine the best possible intervertebral level and window for needle insertion without actual real-time guidance (a highly challenging technique). Imaging of the lumbar spine is significantly easier than that of the thoracic spine, which has narrow interspinous and interlaminar windows, especially at T5-T8 levels.[438] Ultrasonography in the pediatric population is impressive because the vertebral column with limited ossification not only permits visualization of the spinal canal sonoanatomy, but the inserted needle and catheter tip, dural displacement, and the extent of cranial spread can be visualized during a fluid bolus injection in young infants and children (also see Chapter 77).[439,440] Several outcome studies have confirmed the utility of ultrasonography when neuraxial block is performed by the novice and in patients with difficult anatomic landmarks.[441]

Peripheral Nerve Blocks and Ultrasound Guidance for Regional Anesthesia

REBECCA L. JOHNSON, SANDRA L. KOPP, JENS KESSLER, and
ANDREW T. GRAY

KEY POINTS

- Regional anesthesia is only successful when local anesthetic is inserted in close proximity to the targeted nerves. From the inception of regional anesthesia over a century ago, several techniques have been designed and available to facilitate the correct placement of local anesthetic, including the paresthesia-seeking approach, peripheral nerve stimulator, and most recently ultrasound guidance.
- There are no data to support the superiority of one nerve localization technique—paresthesia, nerve stimulation, ultrasound—over another with regard to reducing the risk of nerve injury.
- Ultrasound imaging can elucidate the structure of peripheral nerves and adjacent anatomic structures for regional block. Peripheral nerves have a characteristic honeycomb echotexture, formed by the internal pattern of connective tissue and nerve fibers.
- Ultrasound provides real-time imaging for needle tip placement and drug injection. Successful local anesthetic injections clarify the border of the nerve and track along the nerve path and its branches. Ultrasound guidance results in more consistent procedure times for peripheral nerve blocks and can be applied to many regional anesthesia procedures. Anatomic variation in nerve position and course, which is a potential source of block failure, can be directly visualized.
- Lipid emulsion bolus and infusion improve the success of resuscitation from cardiac arrest because of local anesthetic toxicity if given immediately after a local anesthetic overdose.
- Prior to regional blocks checklists are now being performed in an effort to make rare adverse events even less common, thereby improving patient safety.

Introduction

Peripheral nerve blocks can be performed using a variety of guidance techniques. Recently, ultrasound has gained popularity for regional anesthesia because it allows direct imaging of peripheral nerves, the block needle, and injection distribution. This chapter is a focused update of two chapters on peripheral nerve blockade from the previous edition. The sections to follow contain a selective description of the more common peripheral nerve blocks utilized in clinical practice.

Techniques for Localizing Neural Structures

PARESTHESIA TECHNIQUES

The paresthesia-seeking technique has a long, successful history as a simple method that requires little specialized equipment. A paresthesia is elicited when a needle makes direct contact with a nerve. Paresthesia-seeking techniques are reliant on patient cooperation and participation to guide the needle and local anesthetic injection accurately; therefore only small doses of sedation medication are recommended. Paresthesia techniques have been criticized for causing patient discomfort, although clinical studies have not shown a significant increase in neurologic complications with this technique.[1] Caution should be used when initiating the injection of local anesthetic to ensure that the needle is not intraneural. There is controversy in the literature regarding the use of B-bevel (blunt bevel or short bevel) needles versus sharp needles regarding the incidence and severity of nerve injury if the needle inadvertently punctures or pierces the nerve. Because B-bevel needles have a blunt tip, which is likely to push the nerve aside, they are much less likely to penetrate the nerve; however, when an injury does occur, it appears to be more severe. In contrast, sharp needles are more likely to penetrate the nerve, but the injury appears to be less destructive.[2,3] Success with the paresthesia technique is highly dependent on the skill of the practitioner and requires a thorough understanding of anatomy. This technique was slowly replaced in the 1980s when peripheral nerve stimulation was introduced. Currently, no single technique has been shown to be superior with respect to incidence of neurologic complications.

PERIPHERAL NERVE STIMULATION

Peripheral nerve stimulators deliver small pulses of electric current to the end of a block needle to cause depolarization and muscle contraction when the tip of the needle is in close proximity to a neural structure. This technique allows for localization of a specific peripheral nerve without requiring the elicitation of a paresthesia, thus allowing patients to be more sedated during block placement. It is necessary to attach the cathode (negative terminal) to the stimulating needle and the anode (positive terminal) to the surface of the patient because cathodal stimulation is more efficient than anodal stimulation. Most current-stimulating needles are coated with a thin layer of electrical insulation along the needle shaft with the exception of the tip. This allows for higher current density at the tip of the needle. Higher current output (>1.5 mA) is more likely to stimulate neural structures through tissue or fascial planes and can be associated with painful, vigorous muscle contractions. After localization of the correct motor response, the current is gradually decreased to a current of 0.5 mA or less. A motor response at a current of approximately 0.5 mA is appropriate when used to facilitate the location for injection of local anesthetic or catheter placement.[4] Immediately following injection of local anesthetic or saline (ionic solutions), the current density at the needle tip will rapidly dissipate and the evoked motor response is eliminated (the Raj test)[5].

The stimulating current pulse can be modified to produce a sensory response. The short-duration impulse commonly used (0.1 ms) is effective in stimulating motor fibers, but a longer-duration pulse (0.3 ms) will also stimulate sensory fibers, a useful feature if a pure sensory nerve is being sought.

Ultrasound Guidance

Ultrasound imaging allows direct visualization of peripheral nerves, the block needle tip, and local anesthetic distribution.[6] This imaging modality has proven highly useful for guiding targeted drug injections and catheter placement. This section describes the general principles of ultrasound imaging for regional blocks.

FUNDAMENTAL ASSUMPTIONS AND ARTIFACTS

Ultrasound is sound with a frequency above the audible range (>20,000 cycles per second). The frequencies used in clinical imaging are within the range of 1 to 20 MHz. High-frequency ultrasound beams are well collimated and therefore can provide high resolution. For most regional blocks, the highest frequency is selected that adequately penetrates the depth of field. Sound waves reflected at the interface of two tissues with different acoustic impedances generate echoes. Ambient lighting has a large effect on visual discrimination; therefore dim lighting without glare is especially useful for imaging low-contrast targets such as peripheral nerves.

Ultrasound imaging is predicated on several common assumptions.[7] First, the speed of sound through soft tissue is 1540 m/s, meaning 13 μs elapse for each centimeter of soft tissue traversed back and forth for the total fly-back time of received echoes. This assumption allows interconversion of time and distance for echo ranging. Local heterogeneities in soft tissue can cause artifactual bending of the block needle on ultrasound scans, known as the bayonet artifact (Fig. 46.1).[8,9] Bayonet artifacts are commonly observed during the lateral in-plane approach to popliteal block (see Sciatic Nerve Blocks in the Popliteal Fossa) because more adipose tissue is present over the nerves near the posterior midline of the leg (adipose tissue has a slower speed of sound than the adjacent muscle). The speed of sound artifacts relate both to time-of-flight considerations and to refraction that occurs at the interface of tissues with different speeds of sound.

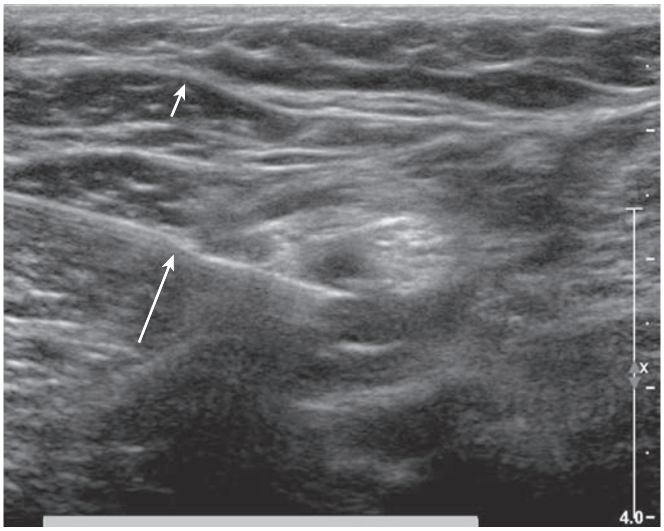

Fig. 46.1 Bayonet artifact is observed during popliteal block of the sciatic nerve. In this sonogram, the block needle appears to bend as it approaches the sciatic nerve in the popliteal fossa *(long arrow)*. The slower speed of sound in the overlying adipose tissue, compared with the adjacent muscle *(short arrow)*, produces this artifact.

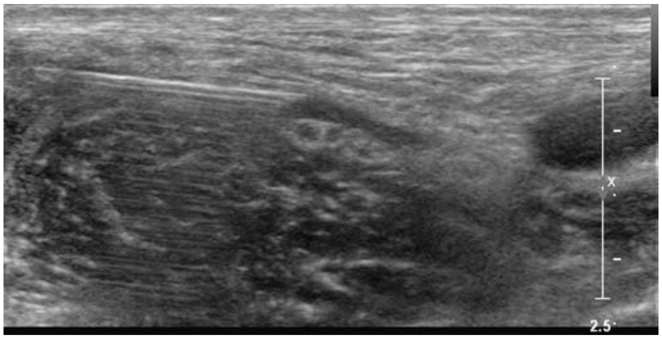

Fig. 46.2 Reverberation artifact is observed during femoral nerve block. Sound waves reverberate back and forth between the walls of the needle and then return later to the transducer. Because the sound waves return at a later time, they are displayed deep within the field of imaging. No reverberation artifact is observed from the needle tip because the bevel opening does not have opposing walls.

Second, ultrasound waves are assumed to take a straight path to and from tissue. When this does not occur, reverberation artifacts are displayed deep to the reflector. Reverberation artifacts are commonly observed from the block needle shaft at shallow angles of insertion because sound waves bounce back and forth between the walls of the needle before returning to the transducer (Fig. 46.2). Comet tail artifact is another type of reverberation artifact and helps identify strong reflectors such as the pleura during supraclavicular and intercostal blocks. At low receiver gain, the comet tail is seen as a tapering series of discrete echo bands just deep

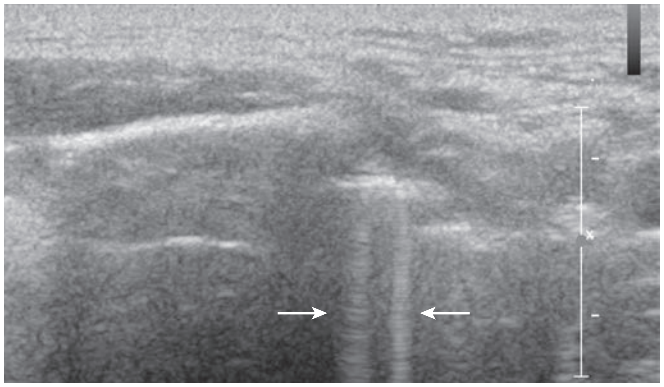

Fig. 46.3 Comet-tail artifact is observed during the scanning of the upper airway *(arrows)*. Small collections of water near the air interface, which also are seen during scanning of the pleura, generate this artifact.

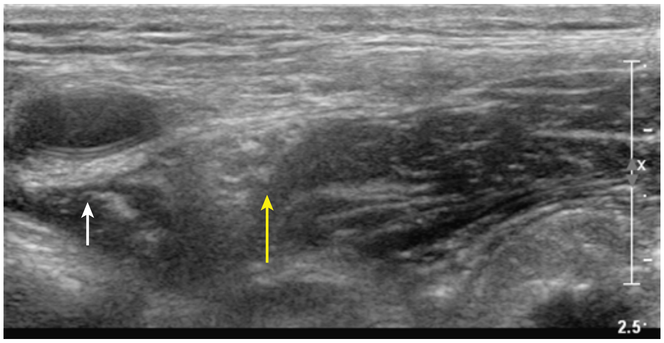

Fig. 46.4 Posterior acoustic enhancement artifact is observed during femoral nerve block. The echoes deep to the femoral artery are enhanced *(white arrow)* and may be incorrectly identified as the femoral nerve *(yellow arrow)*.

to a strongly reflecting structure. The spacing between the bands represents the distance between the anterior and posterior walls of the object.[10] Internal reverberations (arising from within the object) cause the comet tail artifact, most intensely observed when the anatomic object is perpendicular to the beam. Comet tail artifact from the pleura relates to lung water content, because small collections of lung water lined by the strongly reflecting pleura can allow the sound beam to enter and then return at varying times to the transducer (Fig. 46.3).

Third, all reflectors are assumed to be on the central ray of the transducer beam. When this assumption is not true, out-of-plane artifacts are observed (slice thickness artifacts). Definitive proof of out-of-plane artifacts requires multiple views, which are recommended when such ambiguities arise.

Unlike adjacent soft tissue, most biologic fluids do not significantly attenuate the sound beam and therefore cause acoustic enhancement (sometimes referred to as posterior acoustic enhancement or increased through-transmission). Acoustic enhancement artifacts deep to blood vessels can be erroneously interpreted as peripheral nerves (Fig. 46.4). For example, acoustic enhancement deep to the second part of the axillary artery in the axilla can be mistaken for the radial nerve. In the infraclavicular region, acoustic enhancement deep to the axillary artery can be mistaken for the posterior cord of the brachial plexus (and similarly, for the femoral artery and the femoral nerve in the inguinal region).

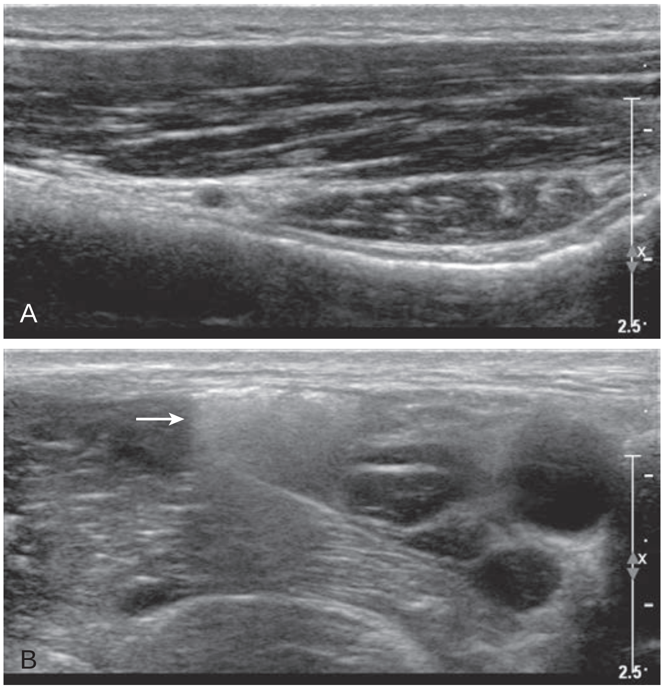

Fig. 46.5 Acoustic shadowing occurs during regional blocks. (A) During block of the axillary nerve in the proximal arm, the cortical surface of the humerus reflects and absorbs sound waves, thereby producing acoustic shadowing deep to the bone surface. (B) During femoral nerve block, air inadvertently injected into the field layers produces strong reflection and acoustic shadowing *(arrow)*.

Acoustic shadowing occurs deep to strong reflecting structures, such as the cortical surface of mature bone (Fig. 46.5). Acoustic shadows from refraction (also termed refractile shadowing or lateral edge shadowing) are often observed deep to the edges of blood vessels when the vessels are imaged in the short-axis view. Refractive edge shadows can be seen from the carotid artery during stellate ganglion block or from the second part of the axillary artery during infraclavicular block. Refraction artifacts (e.g., refractile shadowing) are less apparent when spatial compound imaging (for further information, see later in this chapter) is used to reduce angle-dependent artifacts.

Transducer Selection, Manipulation, and Modes of Imaging

Ultrasound transducers consist of piezoelectric crystals that emit and receive high-frequency sound waves by interconverting electrical and mechanical energy. Transducer selection is important to the success of ultrasound-guided regional anesthesia procedures. High-frequency sound waves provide the best resolution but will not penetrate far into tissue. The frequency range is therefore chosen to be the highest that will allow adequate insonation of the entire depth of field. A low-frequency transducer can be used to image large nerves that lie deep, such as the cords of the

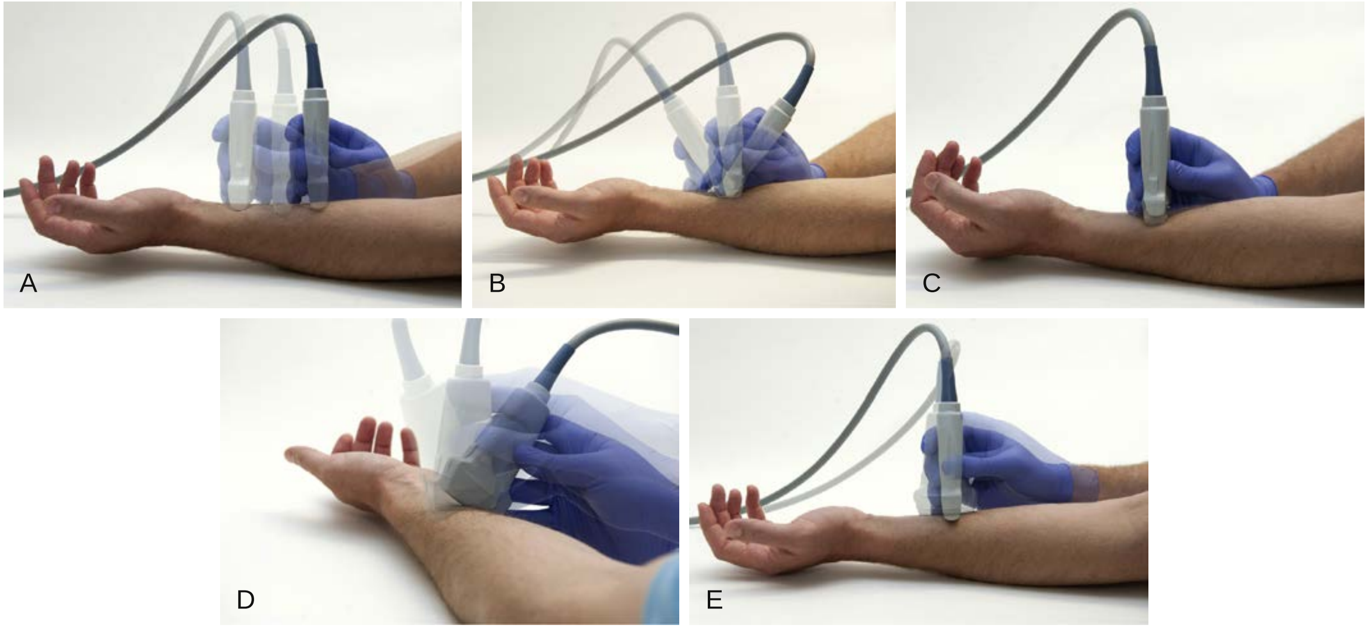

Fig. 46.6 Transducer manipulation. Sliding (A), tilting (B), compression (C), rocking (D), and rotation (E) of the transducer are shown.

brachial plexus that surround the second part of the axillary artery or the proximal sciatic nerve in the gluteal region.

The footprint size (i.e., the length of the active face transducer that contacts the skin) is chosen to provide a broad enough view of the structures of interest. As a general rule, the footprint should be at least as large as the anticipated depth of field. A square or landscape view is better than a keyhole view (i.e., depth greater than footprint) for guidance. As a rule of thumb, for in-plane technique (see Approaches to Regional Block With Ultrasound), every millimeter of the footprint is approximately a millimeter of guidance.

Linear-array transducers generally have a higher scan-line density than curved arrays and therefore produce the best image quality. Images from linear arrays are usually displayed in a rectangular format. When a linear transducer is needed but space at the site of block is limited by anatomic structures such as adjacent bone, a compact linear (hockey stick) transducer that has a smaller footprint can be very useful. Curved arrays provide a broad field of view for a given footprint size and are generally used when space is limited (e.g., infraclavicular region). Curved probes are easier to rock (see Infraclavicular Blocks) and produce images in sector format.

Universal precautions should be used when handling dirty equipment. External surface probes require disinfection between every use and after extended periods of nonuse, per instructions of the manufacturer. Do NOT drop any ultrasound transducer, because the active face of the transducer is especially sensitive to contact with hard surfaces.

One of the essential skills to acquire for regional block with ultrasound is transducer manipulation (Fig. 46.6). For this reason, standardized nomenclature has been established[11]:

- Sliding (moving contact) the transducer along the known course of the nerve using a short-axis view often helps.
- Tilting (cross-plane, side-to-side) will vary the echo brightness of peripheral nerves. Optimizing this angle is critical to promote nerve visibility.
- Compression is often used to confirm venous structures. To improve imaging, compression not only provides better contact, but it also brings the structures closer to the surface of the transducer. Soft tissue is subject to compression; therefore estimates of tissue distances will vary.
- Rocking (in-plane, toward, or away from the indicator) is often necessary to improve visibility of the needle and anatomic structures when the working room is limited.
- Rotation of the probe will produce true short-axis views rather than oblique or long-axis views.

Anisotropy is the change in echogenicity with inclination of the transducer. In general, when objects are obliquely imaged, they appear less echogenic (Fig. 46.7). This relationship is most pronounced for tendons but also occurs for muscle and nerves.[12] Although the term anisotropy was first used to describe changes in received echoes when rocking the transducer with structures viewed in long axis, it has also been used for short-axis views when tilting the transducer. With experience, operators learn to rock and tilt the transducer naturally to fill in the received echoes from peripheral nerves. Sliding and rotating the transducer achieves needle tip localization after optimizing peripheral nerve echoes by tilting.

Spatial compound imaging steers ultrasound beams in different, predetermined angles, typically within approximately 20 degrees from the perpendicular (Fig. 46.8). These multiple lines of insonation are then combined to produce a single composite image. Spatial compound imaging appears to reduce angle-dependent artifacts, anisotropic effects, and acoustic shadows. Another advantage for regional block is that the definition of tissue planes and the detection of nerve borders can be improved. In the systems that have been tested, spatial compound imaging improves needle tip visibility over a limited range of needle insertion angles (<30 degrees). The stray lines of sight (i.e., those that travel off the field underneath the transducer) can be used to form a wider field of view in a trapezoidal format.

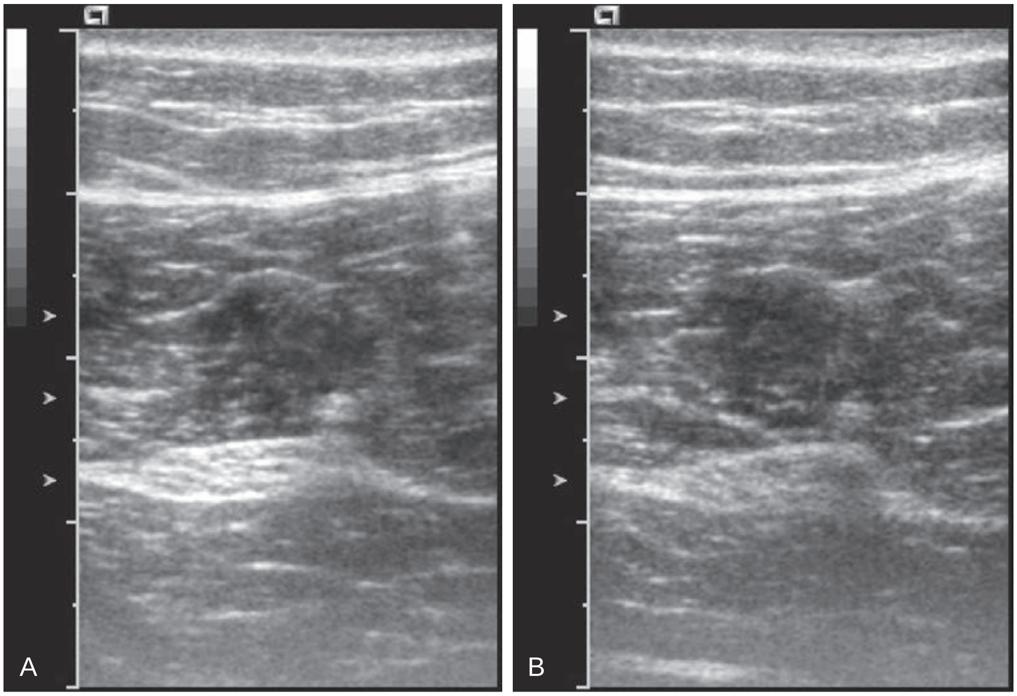

Fig. 46.7 (A) Sciatic nerve imaging in the subgluteal region. (B) The amplitude of the received echoes diminishes when the angle of insonation is changed away from perpendicular to the nerve path, thereby demonstrating anisotropy.

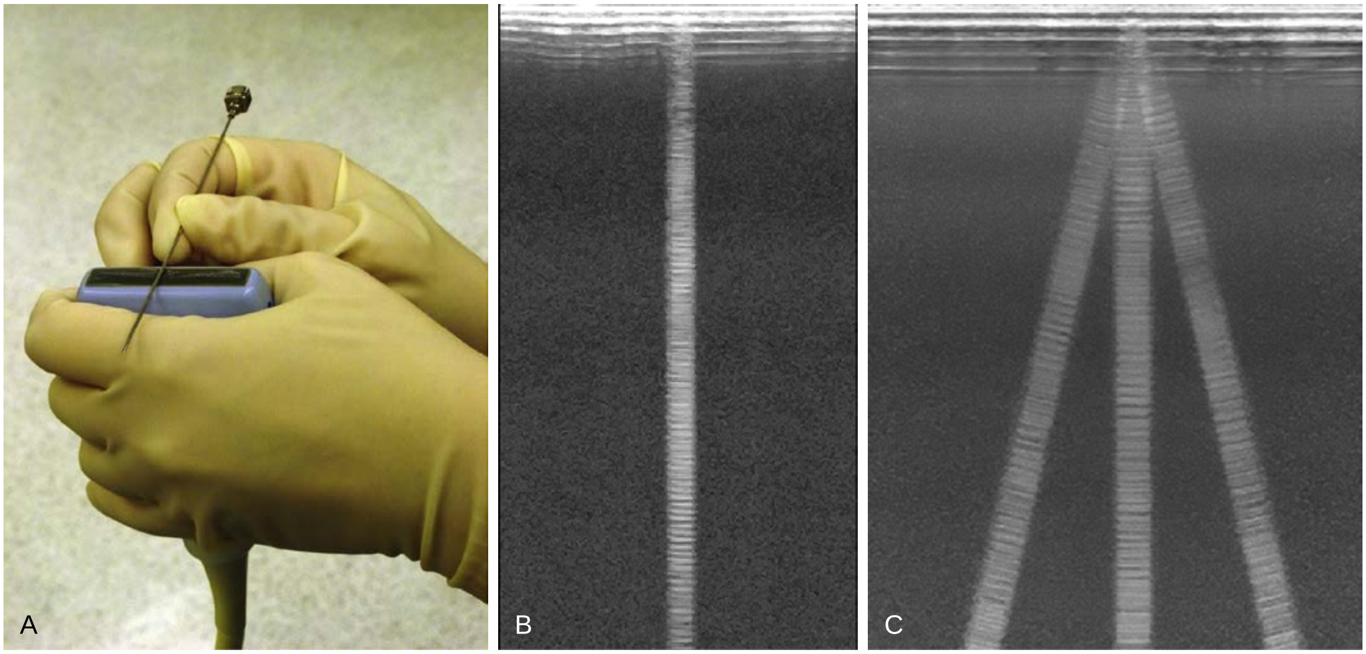

Fig. 46.8 Spatial compound imaging. Some forms of ultrasound imaging use multiple lines of sight by electronically steering the beam to different angles. These sonograms were obtained by placing a linear array test tool (the solid metal stylet of a 17-gauge epidural needle) over the active face of the transducer to isolate a single element. (A) External photograph demonstrates the linear array test tool applied to the active face of the ultrasound transducer. (B) Single-beam imaging is demonstrated. (C) Three lines of sight are used to form a compound image. The test tool images do not display the beam itself, but rather the transmit and receive apertures.

A Doppler shift occurs when a wave source and receiver are moving relative to each other, which produces a change in frequency such that the frequencies of the transmitted and reflected sound waves are not the same. When a wave source and receiver are moving toward each other, the observed frequency is greater than the source frequency; and when moving away from each other, the observed frequency is lower. The change in frequency is related to the velocity of moving reflectors and the angle of insonation. In clinical medicine, red blood cells are the primary reflectors that produce Doppler shifts.

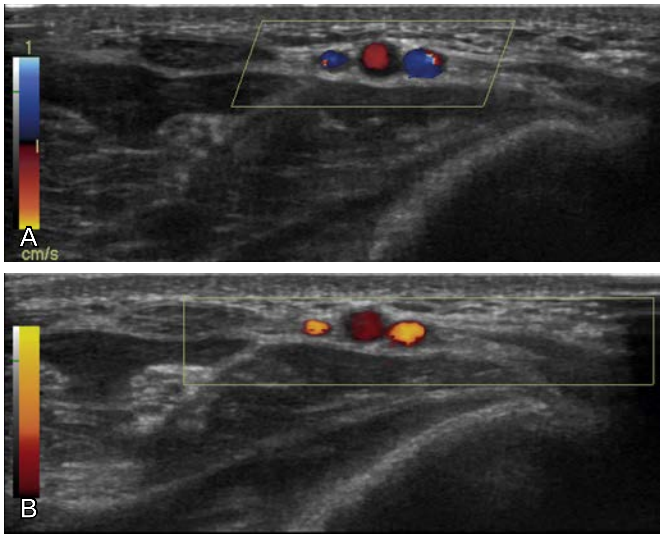

Fig. 46.9 Duplex sonograms illustrate the Doppler shift. (A) In color Doppler, color encoding is based on the mean frequency shift. (B) In power Doppler, color encoding is based on the power spectrum.

Box 46.1 Respective Advantages of Color and Power Doppler Imaging Modalities

Color Doppler

Directional information
Velocity estimates
Less motion artifact (flash artifact)

Power Doppler

More sensitive to detect the presence of flow (by a factor of 3-5 in some cases)
Less angle dependent
No aliasing

Doppler ultrasound imaging has different modes (Fig. 46.9). Traditional color Doppler encodes mean frequency shifts to provide directional velocity information; that is, conventional blue color indicates flow away from the transducer, whereas red color indicates flow toward the transducer. More recently, a more sensitive Doppler technology has been developed that encodes color based on the integration of the Doppler power spectrum.[13] Power Doppler is less angle dependent and not subject to aliasing. The disadvantages are that no directional information is provided and motion sensitivity (flash artifact) is high. Power Doppler is especially useful for detecting small arteries that accompany nerves (Box 46.1). Power Doppler can detect these small arteries and better delineate the course of tortuous vessels that have unfavorable angles to the ultrasound beam.

Needle Tip Visibility

A large number of factors influence needle tip visibility in clinical practice. Metal needles are hyperechoic and can cause reverberation artifact. Needle tip visibility is best when the needle path is parallel to the active face of the transducer. Under this condition, the needle is perpendicular to the sound beam; therefore strong specular reflections will be produced; that is, mirror-like reflections will be produced from a smooth surface. As the angle of incidence is increased, the mean brightness will decrease.[14] In this same study, the bevel angles were ground from 10 to 70 degrees but were found to have no effect on the needle tip echo. However, bevel orientation does influence the needle tip echo; visibility is best with the bevel either directly facing or averting the transducer.[15] Because needle diameters are smaller than the scan plane thickness, larger needles are more echogenic than finer ones.

Visualization of needles in echogenic tissue is difficult, particularly in bright adipose tissue. A number of strategies have been proposed to improve needle tip visibility.[16,17] A low-receiver gain can improve the detection of the needle tip echo. Spatial compound imaging can help identify the needle tip when the needle path is at an angle with respect to the transducer. However, one limitation of this strategy is that only a small triangular section of the field of imaging receives all the lines of sight and is therefore fully compounded. In addition, the range of angles for spatial compound imaging is limited and is usually exceeded by the desired needle insertion path. Rocking back the transducer can improve the angle between the ultrasound beam and needle during in-plane technique (see Approaches to Regional Block with Ultrasound). Most practitioners orient the needle so that the needle bevel faces the transducer.

Among needles originally developed for use in regional anesthesia, Hustead bevels tended to be more visible than side port needles that lack cutting bevels. Needles with echogenic modifications are now commercially marketed for peripheral nerve blocks. One engineering strategy has been to texture the needle surface so that echoes return to the transducer source, regardless of the angle of insonation (Fig. 46.10). One potential limitation of these needle designs is the finite size of the needle texturing. Low-frequency transducers produce longer wavelengths that may be too large to reflect strongly back from the textured surface of the needle.

Approaches to Regional Block With Ultrasound

Peripheral nerves can be directly detected with high-resolution ultrasound imaging.[18] The fascicular echotexture is the most distinguishing feature of nerves (honeycomb architecture) (Fig. 46.11). More central nerves, such as the cervical ventral rami, have fewer fascicles and can appear monofascicular on ultrasound scans. Ultrasound frequencies of 10 MHz or higher are required to distinguish tendons from nerves based on echotexture alone. One of the most powerful techniques to identify nerve fascicles is to slide a broad linear transducer over the known course of a peripheral nerve with the nerve viewed in short axis (transverse cross section).

Nerves can be round, oval, or triangular in shape. Although nerve shape can change along the nerve path, the cross-sectional nerve area is relatively constant in the absence of major branching (Fig. 46.12).[19] Peripheral

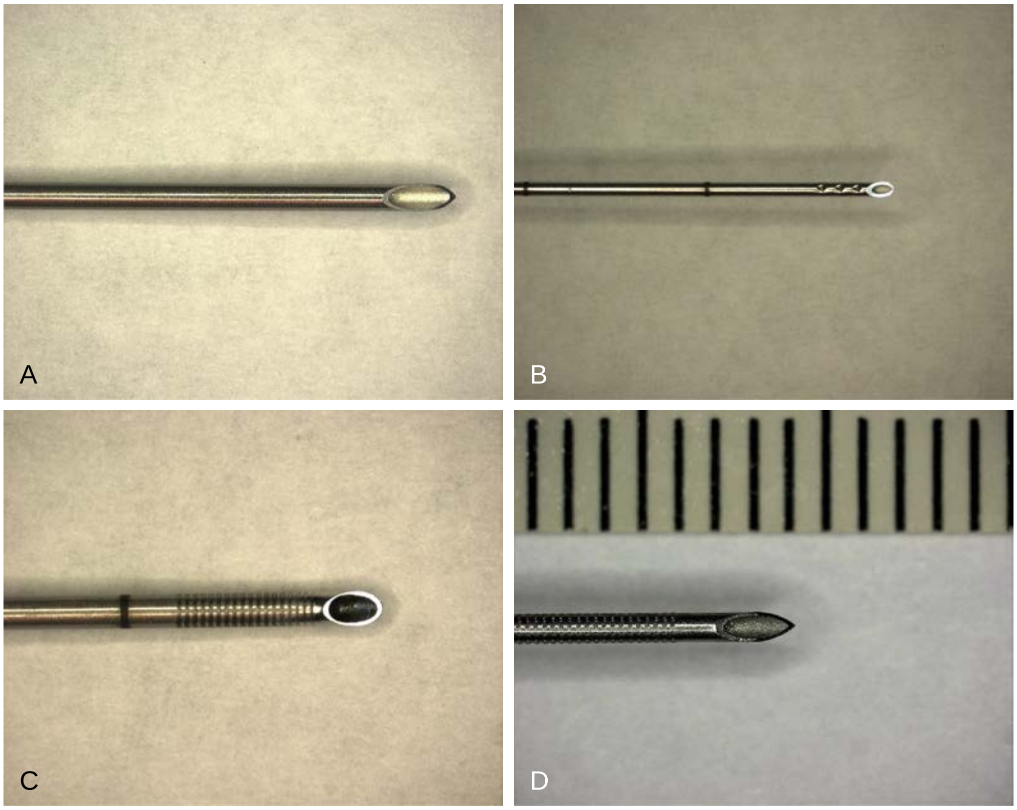

Fig. 46.10 Photomicrographs of needles are used for regional block. A plain conventional needle (A) and echogenic designs (B, C, D) are shown. A smooth needle may not generate a recordable echo because its rounded shaft reflects most incident sound away from the source. A variety of textured surfaces are manufactured and marketed to improve needle tip detection on acquired sonograms. (Modified from Gray AT. *Atlas of Ultrasound-Guided Regional Anesthesia*. 3rd ed. Philadelphia: Saunders; 2018.)

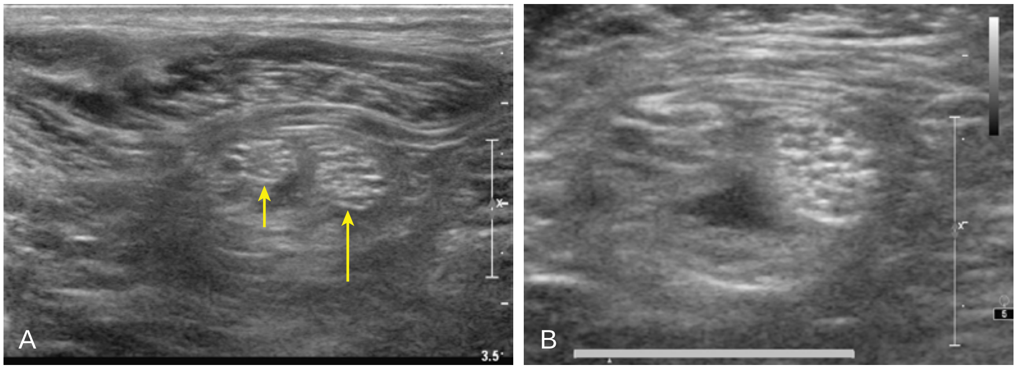

Fig. 46.11 Nerve echotexture. (A) Fascicles of the common peroneal *(short yellow arrow)* and tibial *(long yellow arrow)* nerves are visualized in the popliteal fossa. In this sonogram the honeycomb appearance of a polyfascicular peripheral nerve is observed. (B) Close-up view shows detailed echotexture of the two nerves.

nerves are pathologically enlarged either by entrapment or in certain neuromuscular disorders, such as Charcot-Marie-Tooth, type 1A, disease (Fig. 46.13). Some evidence suggests that patients with diabetic neuropathy also have enlarged peripheral nerves.

Although direct nerve imaging has led to a phenomenal increase in ultrasound-guided regional anesthesia, the identification of other nearby anatomic structures, such as the fascia and other connective tissue, is also critical in this endeavor. These layers permit favorable distribution of local anesthetic, making nerve contact with the block needle unnecessary.

Many approaches to regional blocks with ultrasound are available (Table 46.1). Peripheral nerves are usually viewed in short axis rather than long axis. The needle can approach within the plane of imaging (in-plane technique) or cross the plane of imaging as an echogenic dot (out-of-plane technique). For some regional blocks, offline markings (skin markings before needle insertion) are used instead of online imaging (i.e., imaging during needle insertion and injection). Most studies have suggested that adequate visualization and correct identification of the relevant structures (e.g., peripheral nerve, needle tip, local anesthetic, adjacent anatomic structures) is more important than the

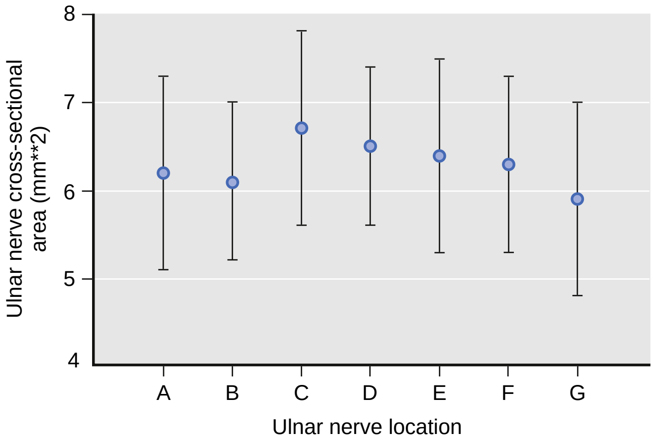

Fig. 46.12 Cross-sectional area of a peripheral nerve as a function of nerve path length. In this figure the cross-sectional area of the ulnar nerve is shown at various points in the upper extremity. Axilla (A); midhumerus (B); 2 cm proximal to medial epicondyle (C); medial epicondyle (D); 2 cm distal to medial epicondyle (E); arterial split (F); and wrist crease (G). Data are shown as mean values with standard deviations. Despite changes in shape that can occur, the cross-sectional area of nerves is relatively constant along the nerve path in the absence of major branching. (Modified from Cartwright MS, Shin HW, Passmore LV, Walker FO. Ultrasonographic findings of the normal ulnar nerve in adults. *Arch Phys Med Rehabil*. 288[3]:394–396, 2007.)

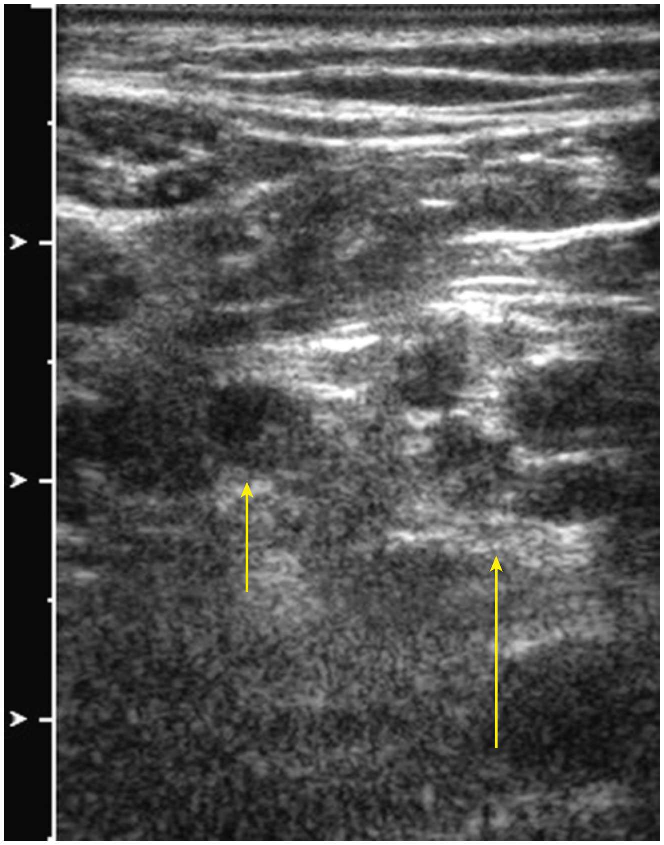

Fig. 46.13 Sonogram demonstrates the popliteal fossa of a patient with Charcot-Marie-Tooth, type 1A, disorder. The peripheral nerves are significantly enlarged because of the large fascicles *(yellow arrows)*. Nerves of the symptomatic and asymptomatic sides can appear similar in these patients. Large tick marks are 10 mm apart.

Table 46.1 Examples of Approaches to Regional Blocks With Ultrasound Guidance

Approach	Examples of Regional Block
Short-axis view, in-plane	Almost any peripheral nerve block Almost any peripheral catheter placement
Short-axis view, out-of-plane	Shallow blocks Interscalene catheter Lateral femoral cutaneous nerve block Femoral nerve catheter placement
Long-axis view, in-plane	Proximal fascia iliaca block Proximal obturator block Anterior sciatic block
Long-axis view, out-of-plane	Epidural placement (longitudinal paramedian view during midline approach) Transtracheal anesthesia

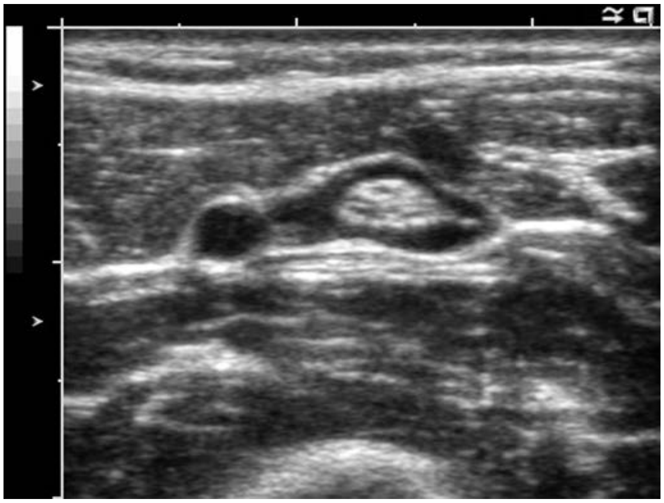

Fig. 46.14 Local anesthetic injection for successful peripheral nerve block. The ulnar nerve and ulnar artery are viewed in short axis in the forearm in this sonogram. The nerve is surrounded with anechoic local anesthetic.

approach, per se, for outcomes after regional blocks. Nevertheless, consistent practice patterns are developing among institutions and illustrate the underlying principles.

Successful injection for peripheral nerve block has typical characteristics (Fig. 46.14). Injections should distribute around the nerve (clarifying the nerve border), travel along the nerve path and branches, and separate the nerve from common anatomic structures such as adjacent arteries that are wrapped together in common fascia and connective tissue. Because anechoic fluid is typically injected, echoes received from the peripheral nerve will also be enhanced by increased through transmission (but not necessarily a sign of block success).

REGIONAL BLOCK TECHNIQUES

Cervical Plexus Blocks

The cervical plexus is derived from the C1, C2, C3, and C4 spinal nerves and supplies branches to the prevertebral muscles, strap muscles of the neck, and phrenic nerve. The deep cervical plexus supplies the musculature of the neck.

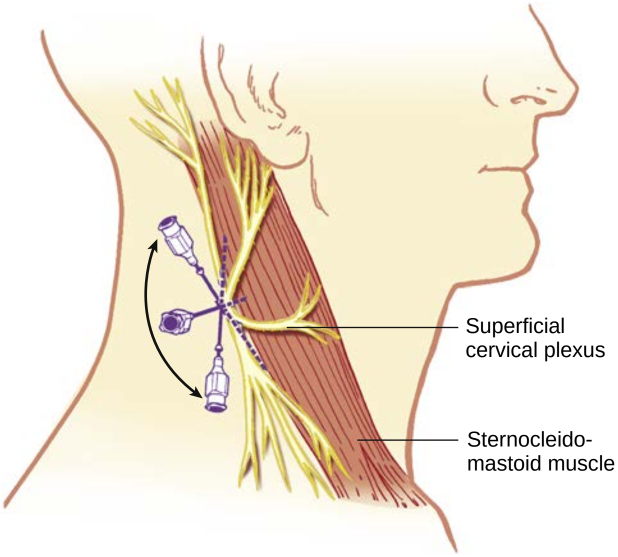

Fig. 46.15 Anatomic landmarks and method of needle placement for a superficial cervical plexus block.

The superficial cervical plexus provides cutaneous sensation of the skin between the trigeminal innervation of the face and the T2 dermatome of the trunk.

Clinical Applications

Blocks of the cervical plexus are easy to perform and provide anesthesia for surgical procedures in the distribution of C2 to C4, including lymph node dissections, plastic surgery repairs, and carotid endarterectomy.[20,21] The ability to continuously monitor the awake patient's neurologic status is an advantage of this anesthetic technique for the latter procedure and has resulted in an upsurge in the popularity of this technique. Bilateral blocks can be used for tracheostomy and thyroidectomy. A variety of approaches to cervical plexus block have been described, including some guided by ultrasound imaging.[22,23]

Superficial Cervical Plexus

The superficial cervical plexus is blocked at the midpoint of the posterior border of the sternocleidomastoid muscle. A skin wheal is made at this point, and a 22-gauge, 4-cm needle is advanced, injecting 5 mL of solution along the posterior border and medial surface of the sternocleidomastoid muscle (Fig. 46.15). It is possible to block the accessory nerve with this injection, resulting in temporary ipsilateral trapezius muscle paralysis. Deep cervical plexus blocks also are possible but have been associated with a higher incidence of respiratory complications.[24]

Brachial Plexus Blocks

BRACHIAL PLEXUS ANATOMY

The brachial plexus is derived from the anterior primary rami of the fifth, sixth, seventh, and eighth cervical nerves and the first thoracic nerve, with variable contributions from the fourth cervical and second thoracic nerves. After leaving their intervertebral foramina, these nerves course anterolaterally and inferiorly to lie between the anterior and middle scalene muscles, which arise from the anterior and posterior tubercles of the cervical vertebra, respectively. The anterior scalene muscle passes caudally and laterally to insert into the scalene tubercle of the first rib; the middle scalene muscle inserts on the first rib posterior to the subclavian artery, which passes between these two scalene muscles along the subclavian groove. The prevertebral fascia invests the anterior and middle scalene muscles, fusing laterally to enclose the brachial plexus in a fascial sheath.

Between the scalene muscles, these nerve roots unite to form three trunks, which emerge from the interscalene space to lie cephaloposterior to the subclavian artery as it courses along the upper surface of the first rib. The superior (C5 and C6), middle (C7), and inferior (C8 and T1) trunks are arranged accordingly and are not in a strict horizontal formation, as often depicted. At the lateral edge of the first rib, each trunk forms anterior and posterior divisions that pass posterior to the midportion of the clavicle to enter the axilla. Within the axilla, these divisions form the lateral, posterior, and medial cords, named for their relationship with the second part of the axillary artery. The superior divisions from the superior and middle trunks form the lateral cord, the inferior divisions from all three trunks form the posterior cord, and the anterior division of the inferior trunk continues as the medial cord.

At the lateral border of the pectoralis minor, the three cords divide into the peripheral nerves of the upper extremity. The lateral cord gives rise to the lateral head of the median nerve and the musculocutaneous nerve; the medial cord gives rise to the medial head of the median nerve, as well as the ulnar, the medial antebrachial, and the medial brachial cutaneous nerves; and the posterior cord divides into the axillary and radial nerves (Fig. 46.16).

Aside from the branches from the cords that form the peripheral nerves as described, several branches arise from the roots of the brachial plexus providing motor innervation to the rhomboid muscles (C5), the subclavian muscles (C5 and C6), and the serratus anterior muscle (C5, C6, and C7). The suprascapular nerve arises from C5 and C6, supplies the muscles of the dorsal aspect of the scapula, and makes a significant contribution to the sensory supply of the shoulder joint.

Sensory distributions of the cervical roots and the peripheral nerves are shown in Fig. 46.17.

Branches arising from the cervical roots were traditionally blocked with the interscalene approach to the brachial plexus. However, interscalene block has a well-documented risk of concomitant phrenic nerve block. This can result in symptomatic hemi-diaphragmatic paralysis and respiratory compromise, especially among those patients with obesity or moderate to severe obstructive pulmonary disease.[25,26] Recent evidence suggests diaphragm paresis may be avoidable with more distal "lung-sparing" block techniques that target the terminal nerves supplying the shoulder joint.

By design, brachial plexus blocks above the clavicle (e.g., interscalene and supraclavicular blocks) primarily target local anesthetic placement near the ventral rami, trunks, and divisions. Blocks below the clavicle (e.g., infraclavicular and axillary blocks) primarily target the cords and terminal nerves.

Interscalene Blocks

The interscalene block is often chosen for regional anesthesia technique of the shoulder[27] in those patients without significant pulmonary disease. Blockade occurs at the level of the superior and middle trunks of the brachial plexus. Although this approach can be used for forearm and hand surgery, blockade of the inferior trunk (C8 and T1) can be incomplete and may require supplementation of the ulnar nerve for adequate surgical anesthesia in that distribution.[28] Ultrasound guidance for interscalene block reduces the chance of inferior trunk sparing.[29]

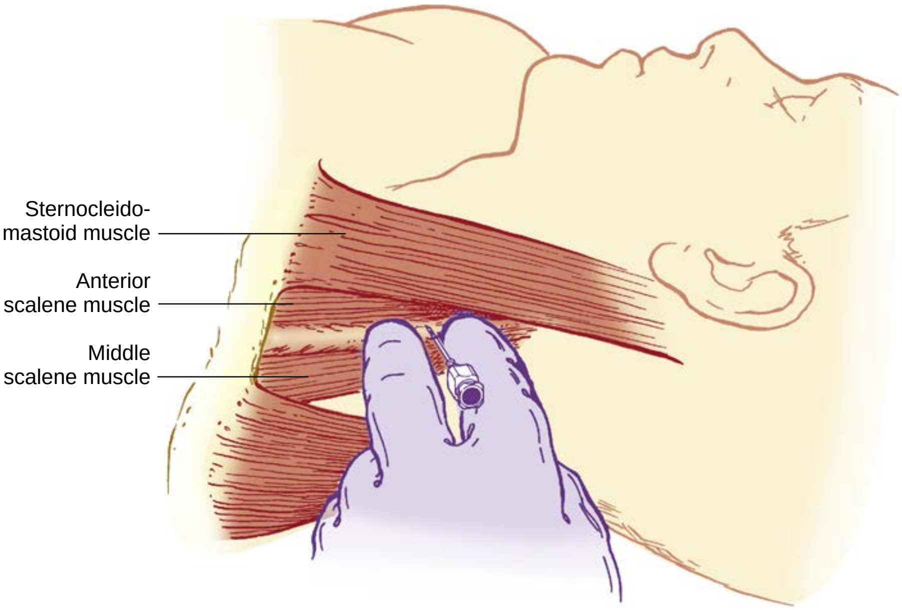

Fig. 46.18 Interscalene block guided by palpation. The fingers palpate the interscalene groove, and the needle is inserted with a caudad and slightly posterior angle.

Several adjacent anatomic structures can serve as important landmarks for performance of interscalene block. The patient should be in the supine position, with the head turned away from the side to be blocked and the patient's arm in any comfortable position. The posterior border of the sternocleidomastoid muscle is readily palpated by having the patient briefly lift the head. The interscalene groove can be palpated by rolling the fingers posterolaterally away from this border over the belly of the anterior scalene muscle into the groove (Fig. 46.18). A line is extended laterally from the cricoid cartilage to intersect the interscalene groove, indicating the level of the transverse process of C6. Although the external jugular vein often overlies this point of intersection, it is not a consistent landmark.

Ultrasound-Guided Technique

Traditional approaches to the interscalene block include paresthesia or peripheral nerve stimulation technique. However, this block is well suited to the use of ultrasound guidance. It is often easiest to obtain a supraclavicular view of the subclavian artery and brachial plexus (Fig. 46.19) and then trace the plexus up the neck with the ultrasound probe until the plexus trunks are visualized as hypoechoic structures between the anterior and medial scalene muscles (the "stoplight" sign[30]). The needle can then be advanced with either an in-plane or out-of-plane approach. After negative aspiration, a small test dose is administered, and local anesthetic spread around the brachial plexus confirms appropriate placement of the needle. Volumes as little as 5 mL may be successful and associated with a decreased frequency of diaphragmatic paresis.[31]

Side Effects and Complications

At the traditional (C6) level of interscalene block, ipsilateral phrenic nerve block and resultant diaphragmatic paresis are inevitable. This effect probably results from the proximity of the phrenic nerve at this level[32] and may cause subjective symptoms of dyspnea. Respiratory compromise can occur in patients with severe preexisting respiratory disease or contralateral phrenic nerve dysfunction.

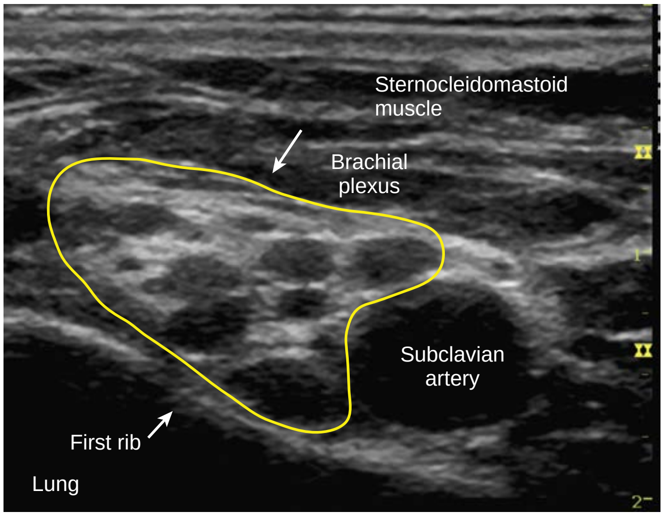

Fig. 46.19 Ultrasound image of the brachial plexus at the level of the first rib.

Involvement of the vagus, recurrent laryngeal, and cervical sympathetic nerves is rarely significant if unilateral, but the patient experiencing symptoms related to these side effects may require reassurance. The risk of pneumothorax is small when the needle is correctly placed at the C5 or C6 level because of the distance from the dome of the pleura.

Severe hypotension and bradycardia (i.e., Bezold-Jarisch reflex) can occur in awake, sitting patients undergoing shoulder surgery under an interscalene block. The cause is presumed to be stimulation of intracardiac mechanoreceptors by decreased venous return, producing an abrupt withdrawal of sympathetic tone and enhanced parasympathetic output. This effect results in bradycardia, hypotension, and syncope. The frequency is decreased when prophylactic β-adrenergic blockers are administered.[33]

Epidural and intrathecal injections can occur with this block. The proximity of significant neurovascular structures may increase the risk of serious neurologic complications when interscalene block is performed in heavily sedated or anesthetized patients. Accordingly, interscalene blocks are usually placed under light sedation in adult patients.

Supraclavicular Blocks. Indications for supraclavicular blocks include operations on the elbow, forearm, and hand. Blockade occurs at the distal trunk–proximal division level of the brachial plexus. At this point, the brachial plexus is relatively compact, and a small volume of local anesthetic produces rapid onset of reliable blockade.

Ultrasound-Guided Technique

The patient is placed in supine position, with the head turned away from the side to be blocked. The arm to be anesthetized is adducted against the side of the body. Similar to interscalene block, traditional approaches to the supraclavicular block include paresthesia or peripheral nerve stimulation. Given the widespread use and availability of ultrasound, this block is now more commonly performed with sonographic guidance. This allows the practitioner to visualize the brachial plexus, subclavian artery, pleura, and first rib. The inherent safety of this technique requires continuous visualization of the needle tip and adjacent anatomic structures during needle advancement.

A high-frequency (15-6 MHz) linear transducer is positioned just proximal to the supraclavicular fossa to obtain a supraclavicular view (see Fig. 46.19). The brachial plexus trunks and divisions are clustered vertically over the first rib on the lateral side of the subclavian artery. The first rib acts as a medial barrier to the needle reaching the pleural dome and is short, wide, and flat.

The needle can then be advanced under direct ultrasound guidance using an in-plane approach from lateral to medial.[34,35] The transducer rests near the clavicle so manipulation can be challenging. Thus advanced skills with needle control are required. After negative aspiration, a small test dose is administered, and local anesthetic spread around the brachial plexus confirms appropriate placement of the needle tip. Volumes as low as 15 to 30 mL may be successful.

Side Effects and Complications

The prevalence of pneumothorax after supraclavicular block is 0.5% to 6% and diminishes with increased experience. Importantly, although the use of ultrasound may decrease the incidence of pneumothorax, the risk has not been eliminated.[36] When this occurs, the onset of symptoms is usually delayed, and it can take up to 24 hours to develop. Thus routine chest radiography after the block is not justified. The supraclavicular approach is best avoided when the patient is uncooperative or cannot tolerate any degree of respiratory compromise. Other complications include phrenic nerve block (as high as 40%-60%), Horner's syndrome, and neuropathy. The presence of phrenic or cervical sympathetic nerve block usually requires only reassurance. Although nerve damage can occur, it is uncommon and usually self-limited.

Suprascapular Nerve Blocks. Suprascapular nerve (SSN) block above the clavicle (anterior approach) is a viable alternative to interscalene block for analgesia of the shoulder region.[37,38] The advantage of this more peripheral approach is that the chance of concomitant phrenic nerve block is significantly reduced. In addition, if the block is semi-selective then other nerves that contribute articular branches to the shoulder joint (e.g., axillary nerve, lateral pectoral nerve) also can be blocked. The anterior approach to SSN block is more shallow (5-10 mm depth) than the more traditional block of the SSN block at the suprascapular notch (20-40 mm depth). Furthermore, the suprascapular notch has variable morphology and in some subjects this landmark is absent. The SSN is the primary sensory innervation of the shoulder joint[39] and is not blocked with approaches to the brachial plexus below the clavicle. Selective low-volume approaches to SSN block above the clavicle also may be useful for pain medicine and rehabilitation.[40]

Indications

The SSN, a mixed-motor and sensory nerve originating from the superior trunk (C5 and C6 nerve roots and often C4 as well) makes a significant contribution to the sensory supply of the shoulder joint. The SSN root may be accessed from within the posterior cervical triangle of the neck where it passes underneath the omohyoid muscle toward the suprascapular notch. The SSN, unlike the suprascapular vessels that remain superficial, then passes deep to the superior transverse scapular ligament exiting through the scapular foramen into the supraspinous fossa finally providing nerve branches to muscles of the shoulder girdle.

Ultrasound-Guided Technique

The anterior SSN block is performed in the supine position with head turned to the contralateral side when accessing the nerve within the posterior cervical triangle (similar positioning as the interscalene nerve block). Alternatively, the patient would be in a seated position to access the scapula for a more distal and posterior SSN block. In the seated position, ask the patient to place his/her hand over to the contralateral shoulder (full shoulder adduction) to move the target (nerve) and scapula lateral from the thorax. Ultrasound guidance is the preferred technique, although a landmark-based method with nerve stimulation for neurolocalization is an option.

Proximal Suprascapular Nerve Block (Anterior Suprascapular Nerve Block). The anterior SSN block technique has emerged as the preferred lung-sparing block alternative to interscalene nerve block.[37,41] A high-frequency linear transducer (15-6 MHz) probe is positioned just proximal to the supraclavicular fossa. Under dynamic scanning, the SSN can be visualized as a round hypoechoic structure deep to the inferior belly of the omohyoid muscle and lateral to the superior trunk in the posterior cervical triangle of the neck (Fig. 46.20) Consider tracing the SSN from its origin (nerve root C5) to facilitate identification. The nerve is then traced more posterior-lateral to a distance away from the superior trunk. A 22-gauge, 5-cm needle is most often selected with shallow 2- to 3-cm depths to the target. Through an out-of-plane or in-plane approach approximately 5 to 15 mL of local anesthetic is deposited deep into omohyoid muscle, but shallow to the prevertebral fascia (higher volumes could result in phrenic nerve blockade). Color Doppler use is advised as the superficial cervical artery and the suprascapular artery, also hypoechoic structures, are strong mimickers of the SSN within the posterior cervical triangle. Auyong and colleagues have shown the anterior SSN block technique provides noninferior, yet lung-sparing, analgesia compared to interscalene nerve block without need for additional terminal nerve block supplementation (e.g., axillary or SSN block).[41]

Shoulder Block (Suprascapular Nerve Plus Axillary [Circumflex] Nerve Block)[42]

In contrast to the anterior suprascapular block, a more distal block of the SSN at the scapula requires the axillary (circumflex) nerve to be also blocked to be remotely comparable to more proximal brachial plexus blockade.[43,44] Unfortunately, the posterior SSN block even with the axillary (circumflex) nerve block will not provide complete anesthesia to the shoulder joint; therefore routinely general anesthesia with supplemental opioid medications would be expected for adequate analgesia.

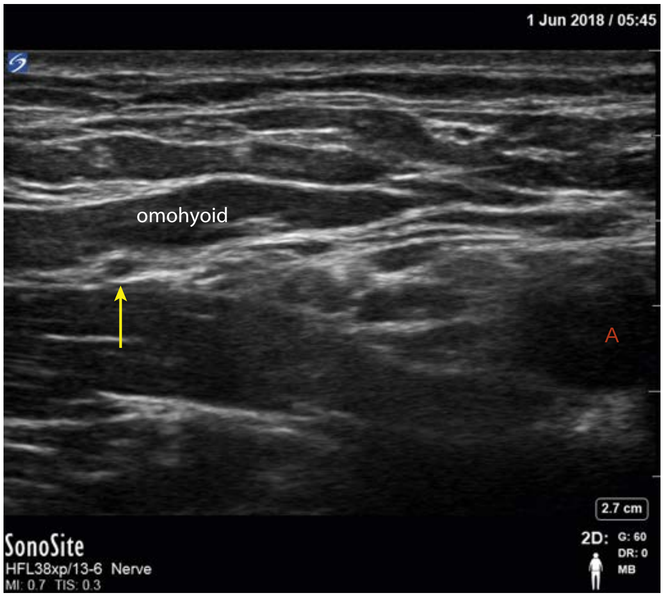

Fig. 46.20 Proximal suprascapular nerve block (anterior suprascapular nerve block). The suprascapular nerve is featured as a round hypoechoic structure deep to the inferior belly of the omohyoid muscle lateral to the superior truck of the brachial plexus within the posterior cervical triangle.

Side Effects and Complications

Serious side effects and complications are primarily due to insertion complications and side effects from local anesthesia use.

Avoid directly targeting the SSN in the suprascapular notch because accidental anterior needle advancement can puncture the pleura. Also, avoid intramuscular placement whether it be avoiding deposit of local anesthesia within the omohyoid (anterior) or within the supraspinatus muscle (posterior), which may result in myotoxicity/myonecrosis. Additionally, the axillary (circumflex) nerve and posterior circumflex artery lie only 2 to 3 mm below the inferior capsule within the neurovascular quadrangular space. Thus a more proximal injection on the posterior upper arm carries a risk of entering the glenohumeral joint space with the block needle and higher local anesthesia volumes have been associated with spread to the posterior cord resulting in radial nerve blockade.

INFRACLAVICULAR BLOCKS

The advantages of the infraclavicular block are that it usually results in complete brachial plexus anesthesia, it is a stable place for a catheter, and no manipulation of the arm is necessary.[45-47] The disadvantages are that the infraclavicular block is a deeper block; therefore needle or probe manipulations are necessary, along with steep angles of needle insertion that result in needle tip visibility issues. Although the arm can remain at the side of the patient, the block is easier when the arm is abducted to straighten the neurovascular bundle. The three arterial wall-hugging cords are named with respect to the second part of the axillary artery; therefore the expected positions are medial, lateral, and posterior. The artery is visualized in short-axis view deep to the pectoralis major and minor muscles (Fig. 46.21). Most practitioners use an in-plane approach from the head of the

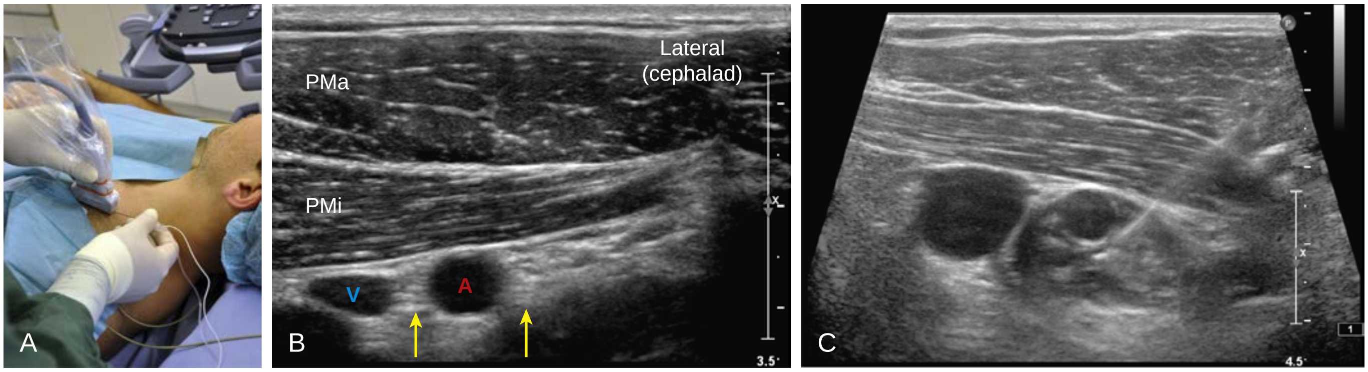

Fig. 46.21 Infraclavicular block with ultrasound imaging. (A) External photograph of the setup for infraclavicular block shows the arm has been abducted in this case. (B) Sonogram of the cords of the brachial plexus *(yellow arrows)* are adjacent to the axillary artery *(A)* and vein *(V)*. The neurovascular bundle lies deep to the pectoralis major *(PMa)* and pectoralis minor *(PMi)* muscles in this anatomic region. (C) Needle tip is in position for infraclavicular block and the resulting local anesthetic distribution.

Table 46.2 Examples of Sonographic Landmarks for Infraclavicular Block

Proximal	Optimal Location	Distal
Cephalic vein	Pectoralis minor muscle (midportion)	Subscapular artery
Thoracoacromial artery	Brachial plexus cords surround axillary artery	Coracobrachialis muscle
Chest wall and pleura	Posterior (or medial) cord underneath axillary artery	Anterior circumflex artery Posterior circumflex artery

Infraclavicular block is usually performed at the level of the second part of the axillary artery (deep to the pectoralis minor muscle). Proximal and distal landmarks along the course of the axillary artery are listed.

Box 46.2 **Sonographic Signs Indicating Infraclavicular Block Success**

- Reduction in axillary artery diameter during injection
- "U-shaped" distribution underneath the axillary artery
- Separation of cords from axillary artery
- *White wall* appearance to the axillary artery (free walls)
- *Dark layer* underneath the axillary artery (long-axis view)

Several studies of clinical block characteristics have validated the high predictive value of local anesthetic distribution underneath the axillary artery for three-cord anesthesia ("U-shaped" distribution).

table or side of the table. The ideal place for local anesthetic distribution to achieve complete infraclavicular block of the brachial plexus is posterior to the axillary artery for single-shot or catheter placement. Substantial evidence suggests that local anesthetic distribution posterior to the axillary artery produces complete brachial plexus block in the infraclavicular region (Table 46.2 and Box 46.2). The cords of the brachial plexus do not need to be directly visualized for successful block. Duplication of the axillary vein is one of the few anatomic variations in the infraclavicular region. The clinical problem is that the accessory vein lies adjacent to the lateral cord of the brachial plexus and near the usual desired position of the needle tip.

AXILLARY BLOCKS

The axillary block is a versatile block for upper extremity anesthesia. Although relatively safe and effective with classical approaches, the cardinal weakness has been the failure to block the musculocutaneous nerve. With the advent of ultrasound imaging, this limitation can be overcome by directly visualizing the musculocutaneous nerve.

The axillary block provides surgical anesthesia of the elbow and more distal upper extremity. The shallow depth of the neurovascular bundle (a 20-mm field is typical) and the large amount of working room make this block relatively easy with ultrasound guidance (Table 46.3). Usually, three arterial wall-hugging branches (median, ulnar, and radial) and one branch with a characteristic medial-to-lateral course in the axilla (musculocutaneous) are visualized. In addition, the musculocutaneous nerve has a characteristic change in shape as it moves from adjacent to the artery (round) to within the coracobrachialis muscle (flat) and then exiting the muscle (triangular).

Table 46.3 Comparison of the Infraclavicular and Axillary Approaches to Brachial Plexus Block

	Infraclavicular Block	Axillary Block
Depth	Deep (two overlying muscles)	Shallow
Onset	Slower	Faster
Tourniquet tolerance	Good	Fair
Catheter success	High	Low

Both in-plane (with needle approaching from the lateral side of the arm) and out-of-plane (with needle approaching from distal to proximal) techniques can be used (Figs. 46.22 and 46.23). The block is performed in the proximal axilla, with the transducer gently pressed against the chest wall to visualize the conjoint tendon of the latissimus dorsi and teres major.[48] A high-frequency linear probe with a small footprint (25–50 mm) with sterile cover can be used for axillary block. The ideal location for local anesthetic injection is between the nerves and the artery so that separation between the two structures occurs to ensure distribution within the neurovascular bundle. These injections result in excellent clinical sensory and motor blocks. The musculocutaneous nerve is usually blocked within the coracobrachialis, where its flat shape gives a large amount of surface area for rapid block. Duplication of the axillary artery and musculocutaneous-median nerve fusion (low-lying lateral cord) are common anatomic variations in the axilla.

Trunk Blocks

INTERCOSTAL NERVE BLOCKS

The intercostal nerves are the primary rami of T1 through T11. T12 is technically the subcostal nerve, and it can communicate with the iliohypogastric and ilioinguinal nerves. Fibers from T1 contribute to the brachial plexus; T2 and T3 provide a few fibers to the formation of the intercostobrachial nerve, which supplies the skin of the medial aspect of the upper arm. Each intercostal nerve has four branches: the gray ramus communicans, which passes anteriorly to the sympathetic ganglion; the posterior cutaneous branch, supplying skin and muscle in the paravertebral area; the lateral cutaneous branch, arising just anterior to the midaxillary line and sending subcutaneous branches anteriorly and posteriorly; and the anterior cutaneous branch, which is the termination of the nerve.

Medial to the posterior angles of the ribs, the intercostal nerves lie between the pleura and the internal intercostal fascia. At the posterior angle of the rib, the nerve lies in the costal groove accompanied by the intercostal vein and artery.

Clinical Applications

Few surgical procedures can be performed with an intercostal block alone, and the application of these blocks in combination with other techniques has largely been supplanted by epidural blockade. However, in patients with contraindications to neuraxial blockade, these techniques can be used alone or combined with other blocks and light

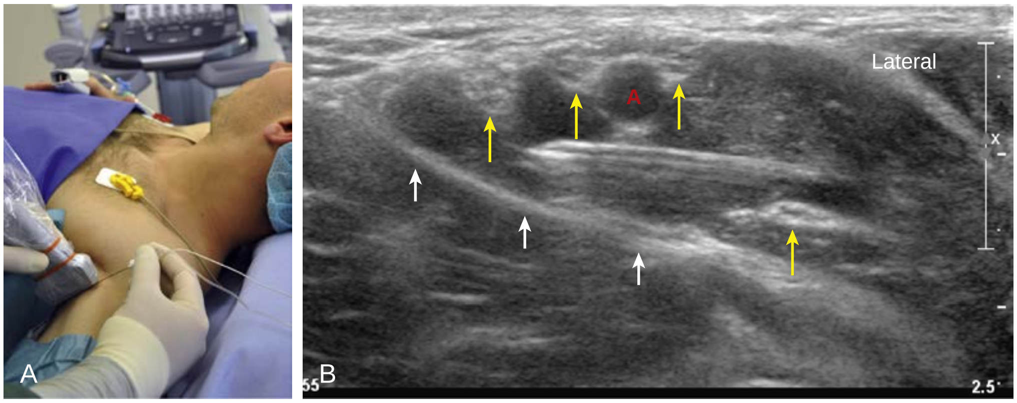

Fig. 46.22 Axillary block with ultrasound guidance. (A) External photograph demonstrates the in-plane approach. (B) Sonogram of the neurovascular bundle in the short-axis view shows the needle tip in-plane after injection of the local anesthetic. The probe compression is just sufficient to coapt the walls of the satellite veins. The block is performed at the level of the conjoint tendon of the latissimus dorsi and teres major *(white arrows)*, which lies under the neurovascular structures. The third part of the axillary artery (A) and nerves of the brachial plexus—radial, ulnar, median, and musculocutaneous—in order from medial to lateral *(yellow arrows)* are shown.

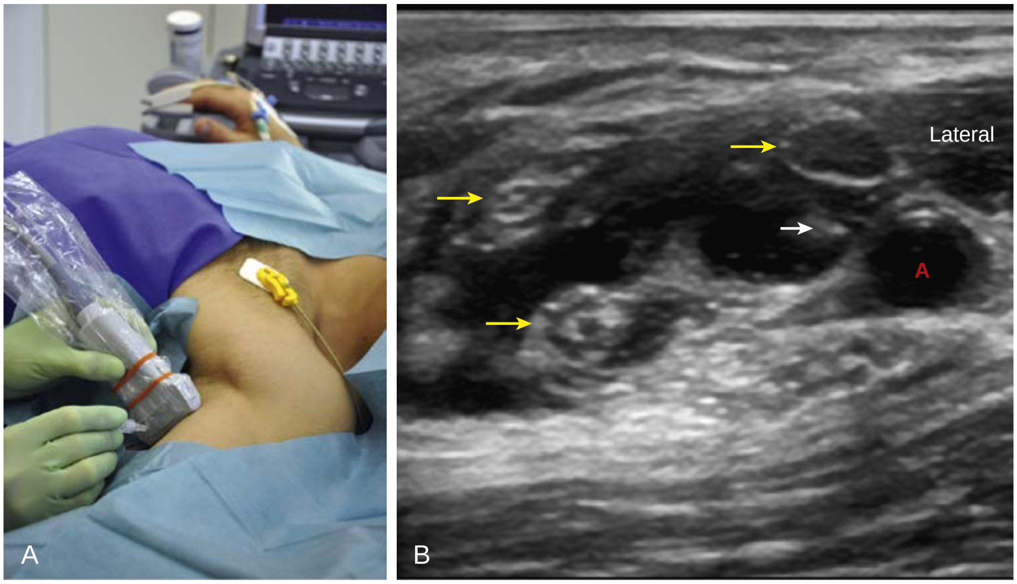

Fig. 46.23 Axillary block with ultrasound guidance. (A) External photograph demonstrates the out-of-plane approach. (B) Sonogram of the neurovascular bundle in the short-axis view shows the needle tip *(white arrow)* crossing the plane of imaging. The probe compression is just sufficient to coapt the walls of the satellite veins. The third part of the axillary artery (A) and nerves of the brachial plexus *(yellow arrows)* are shown.

general anesthesia to provide excellent surgical conditions for intraabdominal procedures. Although surgical applications are possible, the majority of indications are for postoperative analgesia. Intercostal blocks provide a viable alternative to epidural and paravertebral blocks, with a similar safety and efficacy profile.[49]

Intercostal Block Technique

The intercostal nerve can be blocked at the angle of the rib just lateral to the sacrospinalis muscle group. The patient is placed in the prone position with a pillow placed under the abdomen to reduce the lumbar curve (Fig. 46.24). A line is drawn along the posterior vertebral spines. Nearly parallel lines are drawn along the posterior angles of the rib, which can be palpated 6 to 8 cm from the midline. These lines angle medially at the upper levels to prevent overlying of the scapula. The inferior edge of each targeted rib is palpated and is marked on the line intersecting the posterior angle of the rib. After appropriate skin preparation, skin wheals are injected at each of these points. A 22-gauge, short-bevel, 4-cm needle is attached to a 10-mL syringe. Beginning at the lowest marked rib, the index finger of the left hand displaces the skin up over the patient's rib. The needle is inserted at the tip of the finger until it rests on the rib. The fingers of the left hand are shifted to grasp the needle hub firmly. The left hand then walks the needle 3 to 5 mm off the lower rib edge, where 3 to 5 mL of local anesthetic are injected (see Fig. 46.24B and C). This process is repeated at each marked rib. Appropriate intravenous sedation providing analgesia and some degree of amnesia is desirable for the patient's comfort.

Alternatively, intercostal block can be performed in the supine patient at the midaxillary line. Theoretically, the lateral cutaneous branch of the nerve can be missed, but computed tomography studies show that injected solutions spread several centimeters along the costal groove. Further injection of 1 to 2 mL of local anesthetic as the needle is withdrawn blocks the subcutaneous branches.

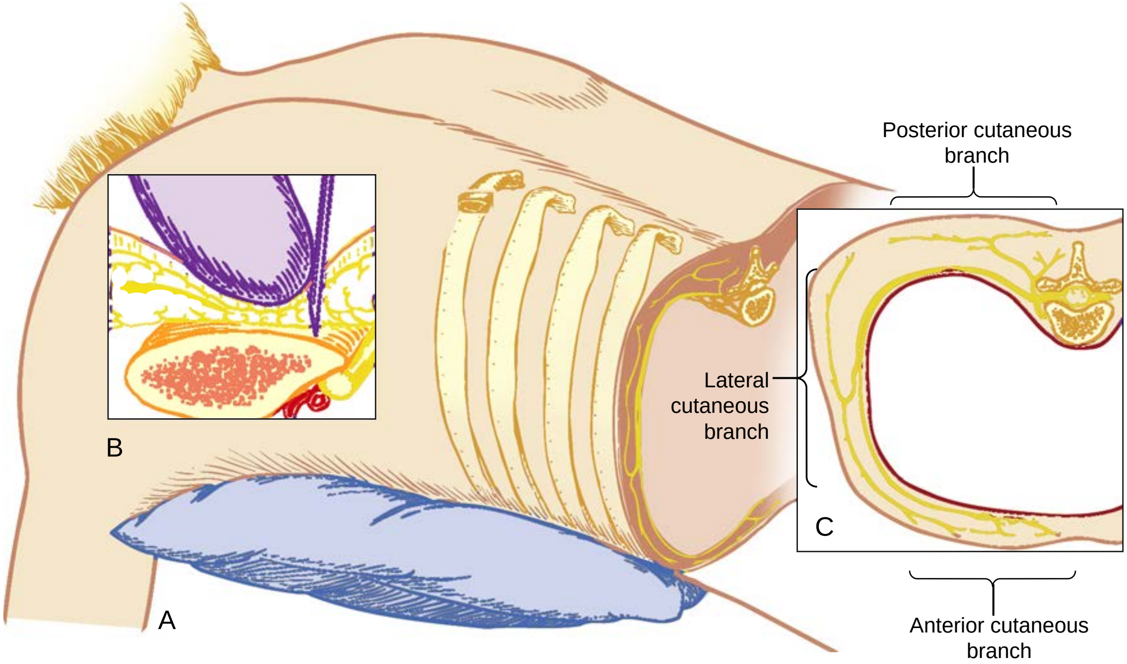

Fig. 46.24 (A) Patient positioning for an intercostal nerve block. (B) The index finger displaces the skin up over the rib. The needle is inserted at the tip of the finger and rests on the rib. The needle is walked off the lower rib edge and inserted 3 to 5 mm. (C) An intercostal nerve and its branches.

Alternative Techniques

Intercostal blocks are possible with ultrasound imaging for guidance. However, the intercostal nerves and vessels are small (about 1-2 mm in diameter) and run in the costal groove and can therefore be difficult to directly image. Similarly, the innermost intercostal muscle, which separates the intercostal nerves and vessels from the internal and external intercostal muscles, is incomplete in the posterior thorax and can be difficult to image.[50] When detected, the innermost intercostal muscle is thin and hypoechoic on ultrasound scans.[51] Intercostal arteries are most visible medially before they enter the costal groove.[52,53] Intercostal arteries are more tortuous in elderly patients, and therefore more exposed and vulnerable to injury.[54]

Intercostal injections dent the pleura, similar to the displacement seen with paravertebral injections.[55] Injections of local anesthetic at the angle of the rib can track medially along the intercostal vessels within the costal groove toward the paravertebral space.[56,57] While variations on ultrasound-guided intercostal nerve blocks have been developed, including anterior approaches to intercostal branches in the serratus plane[58,59] and parasternal region,[60] new technologies are now being developed to improve ultrasound imaging of intercostal nerves and vessels.[61]

Side Effects and Complications

The major complication with intercostal blockade is pneumothorax. The actual incidence, however, was as low as 0.07% in a large series performed by anesthesiologists at all levels of training. Routine postoperative chest radiographs showed an incidence of nonsymptomatic pneumothorax of 0.4% to 1.0%.[62,63] If this unusual complication occurs, treatment is usually limited to observation, administration of oxygen, or needle aspiration. Rarely, chest tube drainage is required.

The risk of systemic local anesthetic toxicity is present with multiple intercostal blocks because of the large volumes and rapid systemic absorption of the solutions. Use of epinephrine has been shown to decrease blood levels. Patients should be monitored and observed carefully during the block and for at least 20 to 30 minutes afterward. Patients with severe pulmonary disease who rely on their intercostal muscles can exhibit respiratory decompensation after bilateral intercostal blockade.

TRANSVERSUS ABDOMINIS PLANE BLOCKS

Four peripheral nerves, the subcostal, ilioinguinal, iliohypogastric, and genitofemoral, primarily innervate the lower abdominal wall. The extended course of the first three nerves through the abdominal wall within the layer between the transversus abdominis and the internal oblique muscles makes this the desired anatomic location for regional block. For ultrasound-guided transversus abdominis plane (TAP) block, the patient is usually in the supine position (Fig. 46.25). The transducer is placed between the iliac crest and costal margin in the midaxillary line. In this location, the muscle layers of the lateral abdominal wall (external oblique, internal oblique, and transversus abdominis) are well defined.

Injection is in the fascial layer that separates the internal oblique and the transversus abdominis muscles. Direct visualization and proximity to the nerves is not critical if 15 to 20 mL of dilute local anesthetic is injected in this layer. The needle approach is in-plane from the anterior side and directed toward the posterolateral corner of the transversus abdominis muscle. The respiratory motion of the peritoneal cavity and influence of muscle contraction makes general anesthesia an appealing option for performing this block. The transversus abdominis muscle is relatively thin; therefore careful placement of the needle tip is necessary.

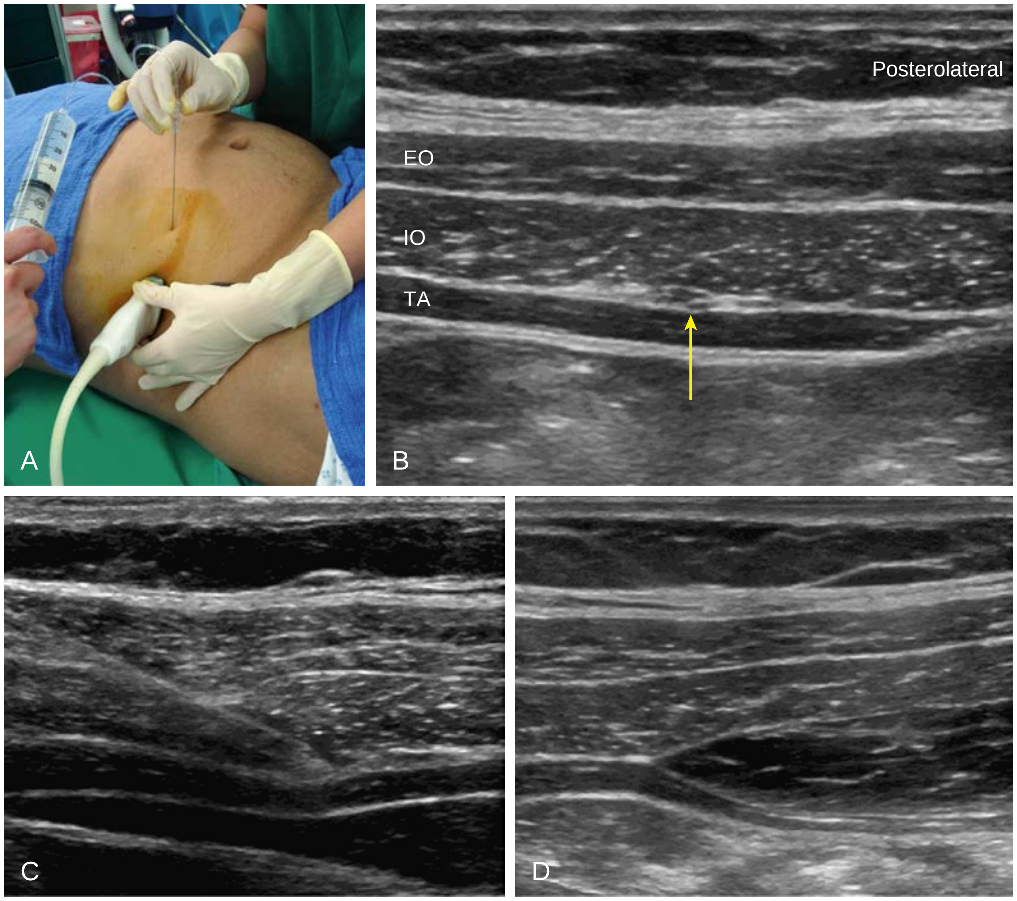

Fig. 46.25 Transversus abdominis plane (TAP) block with ultrasound guidance. (A) Abdominal wall image demonstrates the approach for TAP block. (B) In this sonogram the external oblique *(EO)*, internal oblique *(IO)*, and transversus abdominis *(TA)* muscles are identified (the three-layer-cake appearance). Nerves *(yellow arrow)* are seen entering the plane between the *IO* and *TA* muscles. (C) The needle approaches in-plane and is directed toward the posterolateral edge of the *TA* muscles. (D) The kayak sign demonstrates successful TAP injection. The fascia between the *IO* and *TA* muscles is split apart in the shape resembling a kayak.

ILIOINGUINAL AND ILIOHYPOGASTRIC NERVE BLOCKS

The ilioinguinal and iliohypogastric nerves arise from the first lumbar spinal root. They pierce the transversus abdominis muscle cephalad and medial to the anterior superior iliac spine to lie between the transversus abdominis and internal oblique muscles. After traveling a short distance caudally and medially, their ventral rami pierce the internal oblique muscle before giving off branches, which then pierce the external oblique and provide sensory fibers to the skin. The ilioinguinal nerve courses anteriorly and inferiorly to the inguinal ring, where it exits to supply the skin on the proximal, medial portion of the thigh. The iliohypogastric nerve supplies the skin of the inguinal region.

Indications

Ilioinguinal and iliohypogastric blocks are used for analgesia following inguinal hernia repair and for lower abdominal procedures utilizing a Pfannenstiel incision. These blocks have been shown to reduce pain associated with herniorrhaphy significantly, although they do not provide visceral analgesia, and they cannot be used as the sole anesthetic during surgery. Despite the relatively simple technique, a failure rate as frequent as 10% to 25% has been reported.

Landmark-Based Technique. These blocks can be performed using a loss-of-resistance technique. The local anesthetic should be injected between the transversus abdominis and the internal oblique and between the internal and external oblique muscles.

The anterior superior iliac spine is located and a mark is made 2 cm cephalad and 2 cm medial. A blunt needle is inserted perpendicular to the skin through a small puncture site. Increased resistance is noted as the needle passes into the external oblique muscle. A loss of resistance is then observed as the needle passes through the external oblique muscle to lie between it and the internal oblique muscle. After negative aspiration, 2 mL of local anesthetic is injected. The needle is then inserted further until another loss of resistance is noted as the needle passes out of the internal oblique to lie between it and the transversus abdominis muscle where another 2 mL of local anesthetic is injected. The needle is withdrawn, and the same procedure is repeated two more times in a fan-like distribution between the internal and external oblique and then between the internal oblique and the transversus abdominis muscles. Typically, a total volume of approximately 12 mL of local anesthetic is used.

It is often difficult to appreciate the loss of resistance. Given the potential complications of advancing the needle too far, ultrasound guidance is often used for these

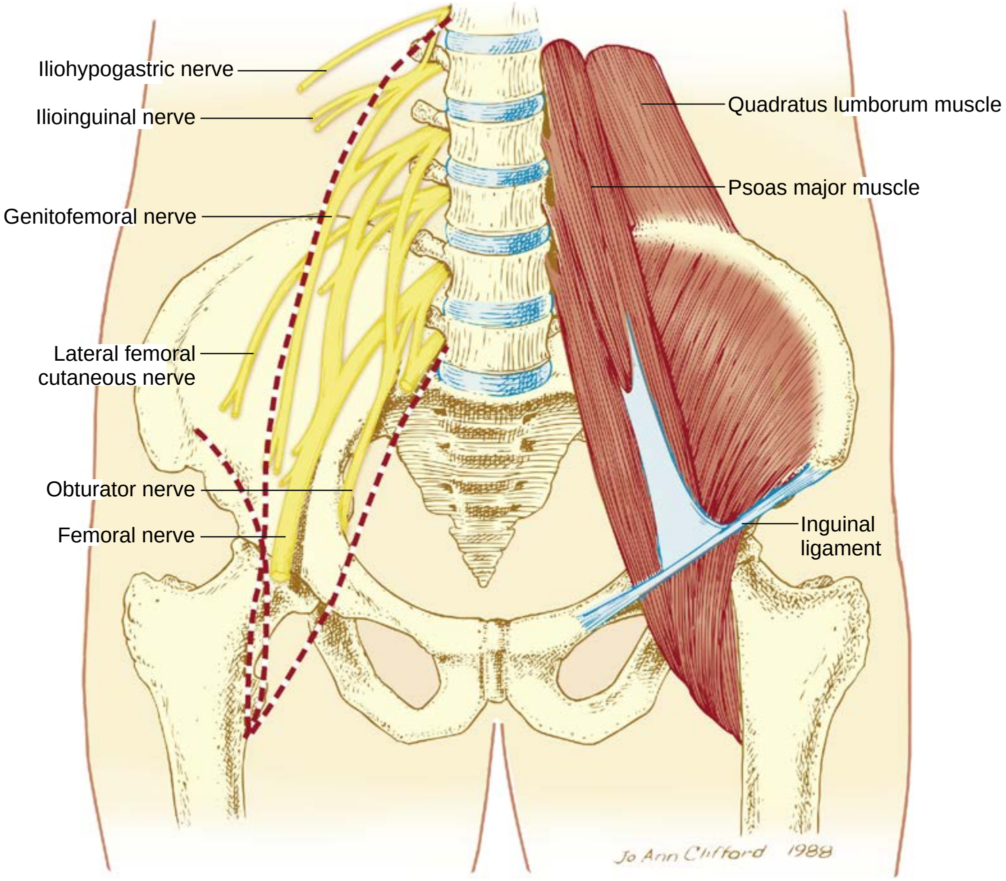

Fig. 46.26 The lumbar plexus lies in the psoas compartment between the psoas major and quadratus lumborum muscles.

blocks.[64,65] The ilioinguinal and iliohypogastric nerves cannot be selectively blocked, even if injection volumes of less than 1 mL are used.[66]

Side Effects and Complications

Blind injection can result in inadvertent injury to the intestine or blood vessels with perforation of the large and small bowel and pelvic hematoma. Lower extremity weakness owing to local anesthetic spread and subsequent femoral nerve blockade can also occur.[66]

Lower Extremity Blocks

LOWER EXTREMITY ANATOMY

The nerve supply to the lower extremity is derived from the lumbar and sacral plexuses. The lumbar plexus is formed by the anterior rami of the first four lumbar nerves, frequently including a branch from T12 and occasionally from L5 (Fig. 46.26). The plexus lies between the psoas major and quadratus lumborum muscles in the psoas compartment. The lower components of the plexus, L2, L3, and L4, primarily innervate the anterior and medial thigh. The anterior divisions of L2, L3, and L4 form the obturator nerve; the posterior divisions of the same components form the femoral nerve; and the lateral femoral cutaneous nerve is formed from posterior divisions of L2 and L3.

The sacral plexus gives off two nerves that are important for lower extremity surgery: the posterior cutaneous nerve of the thigh and the sciatic nerve. The posterior cutaneous nerve of the thigh and the sciatic nerve are derived from the first, second, and third sacral nerves plus branches from the anterior rami of L4 and L5, respectively. These nerves pass through the pelvis together and are blocked by the same technique. The sciatic nerve is a combination of two major nerve trunks, the tibial (i.e., ventral branches of the anterior rami of L4, L5, S1, S2, and S3) and the common peroneal (i.e., dorsal branches of the anterior rami of L4, L5, S1, S2, and S3), which form the sciatic nerve. The trunks separate at or above the popliteal fossa, with the tibial nerve passing medially and the common peroneal laterally. The cutaneous distributions of the lumbosacral and peripheral nerves are shown in Fig. 46.27.

FEMORAL NERVE BLOCKS

The advantages of using ultrasound to guide femoral nerve block include a more complete block, local anesthetic volume sparing, and fewer side effects such as vascular punctures. The femoral nerve usually lies lateral to the femoral artery in the groove formed by the iliacus and psoas muscles. The nerve can be oval or triangular in cross-sectional shape with an anteroposterior diameter of approximately 3 mm and a mediolateral diameter of 10 mm. The best depiction of the femoral nerve is from 10 cm proximal to 5 cm distal to the inguinal ligament. According to the pelvic

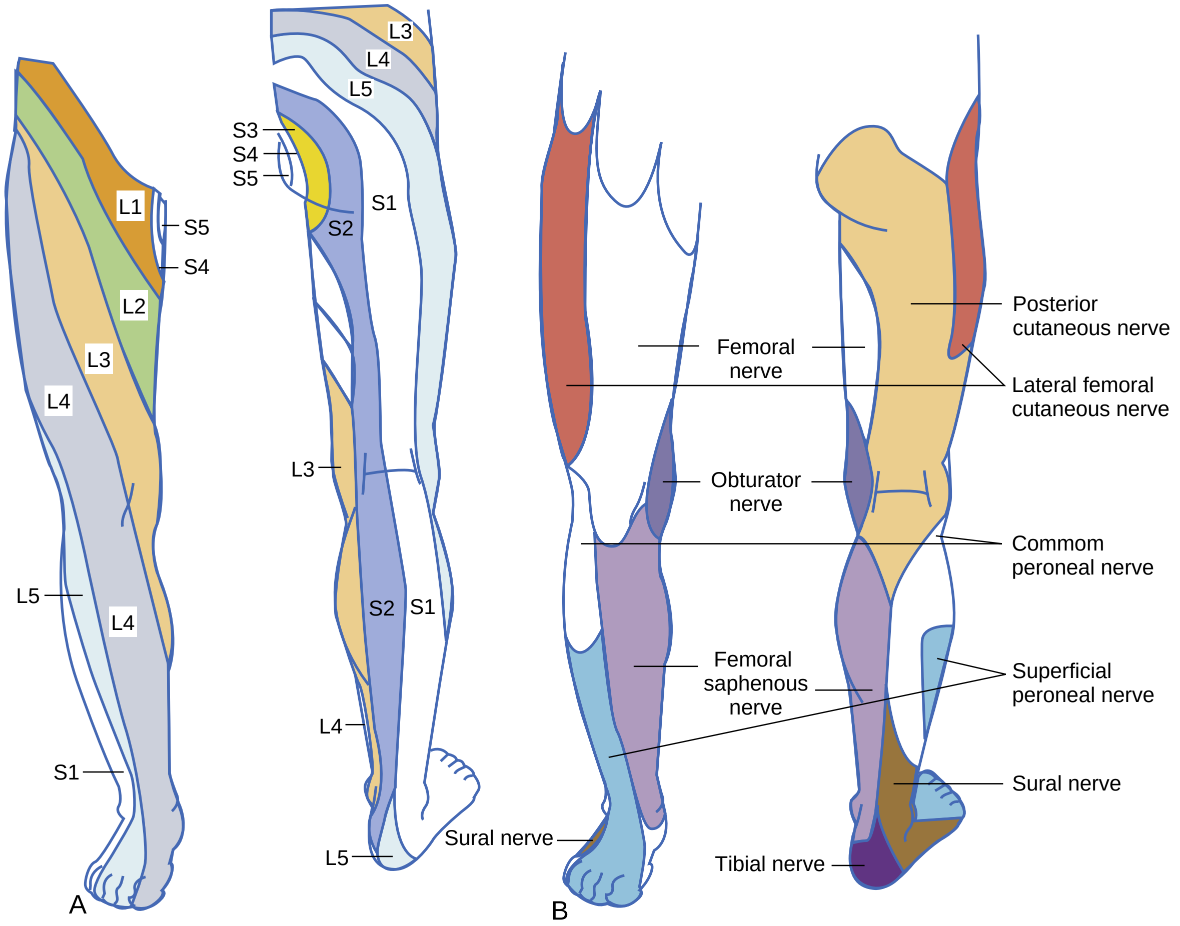

Fig. 46.27 (A) Cutaneous distribution of the lumbosacral nerves. (B) Cutaneous distribution of the peripheral nerves of the lower extremity.

inclination, some tilting of the ultrasound probe is necessary for the sound beam to meet the nerve perpendicularly for optimal scanning. In addition, the femoral nerve has a slight medial-to-lateral course; therefore some rotation of the probe is also necessary for the best view of the nerve. Because the femoral nerve is covered by echobright adipose tissue and fascia, the echogenic outer sheath of the nerve is difficult to establish. In some patients, the psoas tendon can appear similar to the femoral nerve. However, the psoas tendon lies deep within the muscle. If the profunda femoris artery (i.e., the deep branch of the femoral artery) is visualized, then the transducer is usually too distal for complete femoral nerve block. The femoral nerve is often identified as a slight indentation in the surface of the iliacus and psoas muscles.

For femoral nerve block, a broad (35-50 mm footprint) linear transducer is used (Fig. 46.28). Both in-plane (from lateral to medial) and out-of-plane (from distal to proximal) approaches can be used. The advantage of the in-plane approach is visualization of the approaching needle. The disadvantages are the longer needle path and a tendency of the needle to skim over the fascia iliaca by deforming it rather than puncturing it. The out-of-plane approach is often used for catheter placement.

For either approach, the needle tip is positioned between the fascia iliaca and the iliopsoas muscle near the lateral corner of the femoral nerve to avoid the femoral vessels, similar to the method for fascia iliaca block. The fascia iliaca has a characteristic mediolateral slant. The desired distribution is local anesthetic layering under or completely around the femoral nerve. When layering of local anesthetic is restricted over the nerve, the concern is that the fascia iliaca is intact and that block failure will result. In the obese patient, femoral nerve imaging is challenging and ultrasound can therefore be combined with nerve stimulation for successful block in these patients. After successful injection of a local anesthetic, distal branches of the femoral nerve can be appreciated by sliding the transducer along the known course of the nerve.

Fascia Iliaca (Modified Femoral Nerve) Blocks

Technique. The fascia iliaca block was originally described in children and involved detection of a double pop sensation as the needle traverses the fascia lata and fascia iliaca of the thigh (see also Chapter 77).[67] Penetration of both layers of fascia is important for block success. To facilitate the appreciation of the "clicks" or "pops," the use of a short-bevel or bullet-tipped needle has been advocated to provide more tactile feedback than with cutting needles.

Because the fascia iliaca invests the iliopsoas muscle and femoral nerve, high volumes of dilute long-acting local anesthetic can be injected to block nerves of the lumbar plexus via this anterior approach. The clinical applications for fascia iliaca block are similar as those for femoral nerve block.[68]

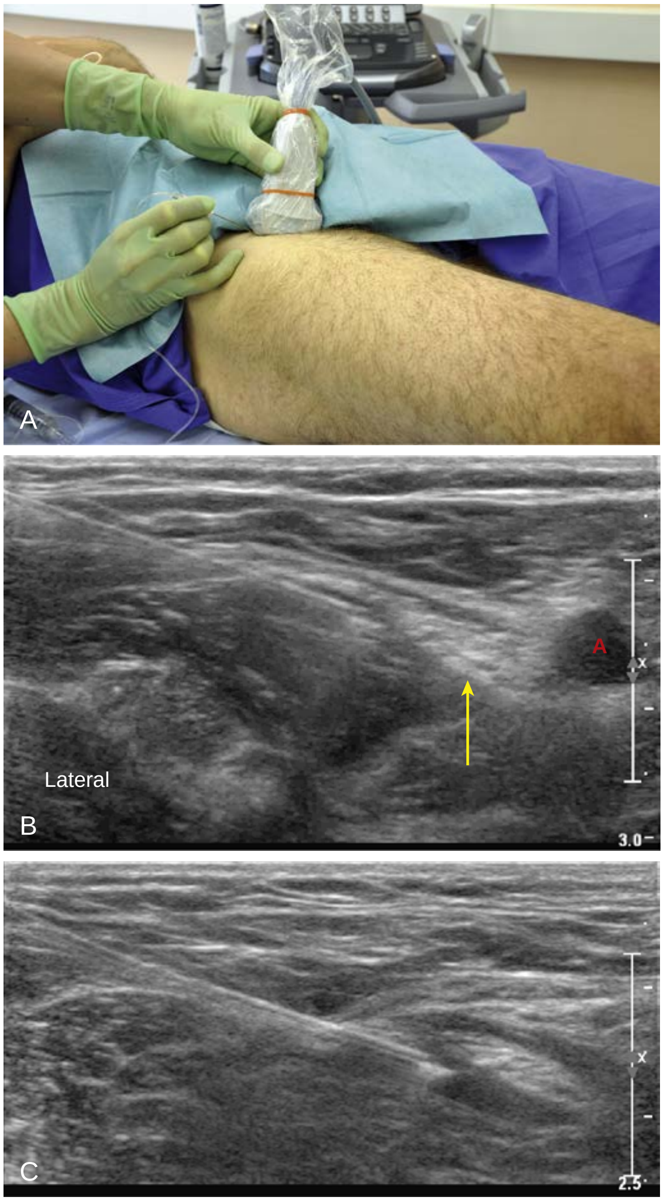

Fig. 46.28 Femoral nerve block with ultrasound imaging (in-plane approach). (A) External photograph shows the setup for femoral nerve block. (B) The needle tip is in position before injecting adjacent to the femoral nerve *(yellow arrow)*. The femoral nerve lies lateral to the femoral artery (A). (C) Local anesthetic surrounds the femoral nerve after injection. (Modified from Gray AT. *Atlas of Ultrasound-Guided Regional Anesthesia*. 3rd ed. Philadelphia: Saunders; 2018.)

The needle entry site for the fascia iliaca block is determined by drawing a line between the pubic tubercle and the anterior superior iliac spine and dividing this line into thirds. The needle entry point is 1 cm caudal to the intersection of the medial two thirds and lateral one third along this line. This site is well away from the femoral artery, which is useful for patients in whom femoral artery puncture is contraindicated. Ultrasound can also be used to visualize the two fascial layers and monitor the spread of local anesthetic beneath the fascia iliaca.[69,70]

Side Effects and Complications. Intravascular injection and hematoma are possible because of the proximity of the femoral artery. Anatomically, the femoral nerve and artery are located in separate sheaths approximately 1 cm apart. In most patients with normal anatomy, the femoral artery can be easily palpated, allowing correct, safe needle positioning lateral to the pulsation. The presence of femoral vascular grafts is a relative contraindication to these techniques, but these grafts are easily identified with ultrasound imaging in most cases. Because the injection is made between the femoral and lateral femoral cutaneous nerves, nerve damage is rare.

SAPHENOUS NERVE BLOCKS ABOVE THE KNEE (INCLUDING ADDUCTOR CANAL BLOCK)

Indications

Several approaches to the saphenous nerve block have been described using an above-the-knee approach. When used in combination with multimodal analgesia, a saphenous nerve block at or near the mid-thigh can be as effective or in some studies preferable to a femoral nerve block following knee surgery because of reduced rates of quadriceps weakness.[71-73] The correct "adductor canal block" location is a source of active debate even though the putative anatomic targets may be separated by mere inches. The "true" adductor canal block may best be determined with ultrasound by identifying the medial border of the sartorius muscle converging with the medial border of the adductor longus muscle.[74] A double contour is appreciated on the roof of the canal, which denotes the vastoadductor membrane. This anatomic distinction holds importance as the nerve to the vastus medialis often lies outside the adductor canal in a distinct fascial sheath. Hence a too distal adductor canal block within the "true" adductor canal may miss the nerve to the vastus medialis, a major contributor to knee joint pain following total knee arthroplasty. Jaeger and colleagues advocate for a periarterial injection of local anesthesia lateral to the femoral artery under the sartorius muscle deep to the vastoadductor membrane midway between the anterior superior iliac spine and the patella where local anesthetic is likely to bathe both the saphenous nerve and the nerve to the vastus medialis.[71]

Anatomy

As the saphenous nerve is a terminal sensory branch of the femoral nerve above the knee, it supplies innervation to the infrapatellar branches to the knee joint. It pierces the fascia lata between the tendons of the sartorius and gracilis muscles before it runs in the adductor canal along the posterior border of the sartorius muscle. The nerve emerges and divides at the level of the knee before continuing distally along the medial border of the lower leg.

Technique

Adductor canal block is performed in the supine position with thigh positioned in slight external rotation with leg extended to expose the inner thigh. Ultrasound guidance is the preferred neurolocalization technique, although nerve stimulation would also be an option or both used in combination.

Ultrasound-Guided Technique. A high-frequency linear transducer (15-6 MHz) probe is positioned transverse on the anteromedial thigh, which is scanned in short-axis beginning at the junction between the middle and distal thirds of the thigh. The thick vastoadductor membrane

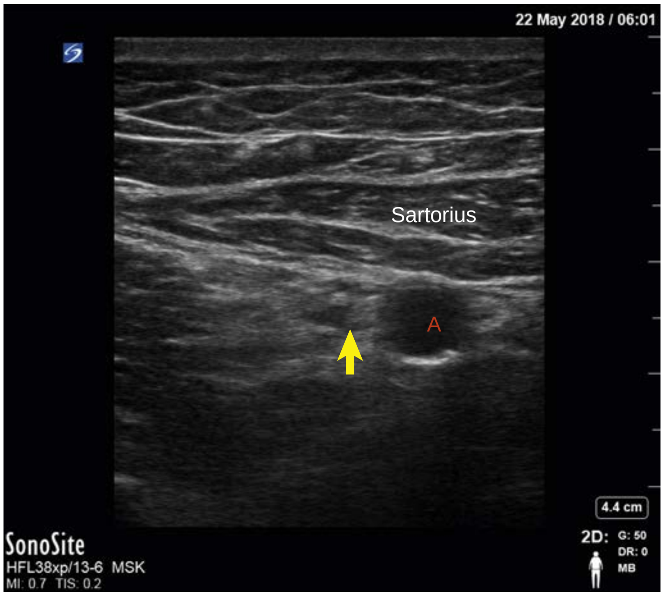

Fig. 46.29 Proximal saphenous nerve block (adductor canal block). Sonographically, the adductor canal block may best be determined by identifying the converging borders between the vastus medialis muscle (lateral), sartorius muscle (anterior), and femoral artery (most medial). Periarterial deposit of local anesthesia is desired lateral to the femoral artery midway between the anterior superior iliac spine and the patella.

defines the border between vastus medialis muscle (lateral), sartorius muscle (anterior), and femoral artery (most medial) (Fig. 46.29). A 22-gauge, 5-cm needle is most often selected with 2- to 3-cm depths to the target. Through an in-plane approach approximately 10 to 15 mL of local anesthetic (higher volumes may result in quadriceps paresis)[75] is injected lateral to the artery, deep to the sartorius muscle.

Side Effects and Complications

The risks of complications with this block are low, although the same theoretical risks with all regional anesthetic techniques apply to this block. Vascular injury leading to arterial pseudoaneurysm is possible. Intramuscular spread of local anesthetic should be avoided as cases of myonecrosis have been reported[76] and unexpected thigh weakness should prompt evaluation. Although adductor canal block is considered among the more selective "muscle-sparing" peripheral blocks of the lower extremity, caution is still advised and fall prevention strategies are important, including patient education on avoidance of unsupported ambulation.[77]

SAPHENOUS NERVE BLOCKS BELOW THE KNEE

Indications

The saphenous nerve provides innervation to the medial aspect of the lower extremity from the knee to the medial malleolus. Saphenous nerve blocks are commonly combined with popliteal and ankle blockade. Several approaches to the saphenous nerve block have been described, including a paravenous (below the knee) approach. Ultrasound guidance can be used for this technique. The saphenous nerve can be blocked at the level of the ankle and can be combined with other injections for ankle block.

Anatomy

The saphenous nerve emerges from the adductor canal hiatus and divides at the level of the knee before continuing distally along the medial border of the tibia, posterior to the great saphenous vein. The saphenous nerve is located approximately 1 cm medial and 1 cm posterior to the saphenous vein at the level of the tibial tuberosity.

Technique

The saphenous nerve at this point is purely sensory; therefore a field block technique is possible and likely equally effective to nerve stimulation. Ultrasound guidance has gained significant popularity as a tool to identify the neural and vascular structures that lie in close proximity to the saphenous nerve.

Paravenous Approach. At the level of the tibial tuberosity, approximately 5 to 10 mL of local anesthetic is infiltrated deep to the great saphenous vein.

Localized Field Block. Approximately 5 to 10 mL of local anesthetic may be infiltrated from the medial condyle of the tibia anteriorly to the tibial tuberosity and posteriorly to the medial head of the gastrocnemius muscle. Success rates for this technique range from 33% to 65%.

Side Effects and Complications

The risks of complications with this block are low, although the same risk pattern for all regional anesthetic techniques apply to this block; that is, nerve or tissue damage and vascular puncture with hematoma formation. Given that the great saphenous vein is used as a landmark for the field block technique, minor hematoma formation is not uncommon.

SCIATIC NERVE BLOCKS IN THE POPLITEAL FOSSA

The sciatic nerve can be blocked anywhere along its course from the gluteal region to the popliteal fossa.[78-80] Many approaches have been described, including those from the anterior aspect of the thigh.[81] One of the most common approaches is to block the sciatic nerve in the popliteal fossa using a lateral approach in supine position with the leg elevated.[82] In this anatomic location, the block can be performed close to the skin surface. The division of the sciatic nerve provides a broad target with large surface area to promote clinical block characteristics. For this technique, the needle tip is positioned between the tibial and common peroneal components of the sciatic nerve near the division so that a single injection distributes to both nerves (Fig. 46.30). By sliding the transducer along the known course of the sciatic nerve, its characteristic division in the popliteal fossa can be identified. This method of sliding assessment is also important to verify the local anesthetic distribution after injection. The tibial nerve has a straighter course than the common peroneal nerve and has approximately twice the cross-sectional area. The tibial nerve lies posterior to the popliteal artery and vein at the popliteal crease, and this location can be a useful starting point when imaging is difficult. When the foot is moved, the nerves of the popliteal fossa have characteristic motions that can be helpful for nerve identification in some patients. The advantages of this

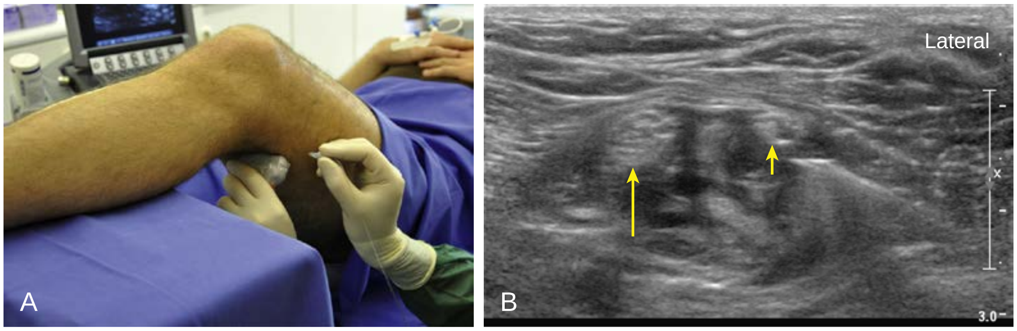

Fig. 46.30 Popliteal block with ultrasound imaging (in-plane approach). (A) External photograph shows the setup for popliteal nerve block in the supine position. The leg is elevated, and the transducer is applied to the posterior surface of the leg. (B) The needle approaches the bifurcation of the sciatic nerve in the plane of imaging from the lateral aspect of the leg. The needle tip is positioned between the tibial *(long yellow arrow)* and common peroneal *(short yellow arrow)* nerves.

approach are the convenient position, the transducer position is remote from the site of needle entry, and the parallel in-plane approach of the block needle results in optimal needle tip visibility. After injection, following the local anesthetic distribution around and along the nerve path (Fig. 46.31) is relatively easy.

ALTERNATIVE APPROACHES TO SCIATIC NERVE BLOCK

The sciatic nerve can be blocked anywhere along its course. However, approaches proximal to the popliteal fossa are usually more difficult because the nerve lies deeper from the skin surface. The sciatic nerve is a mobile structure with position and orientation varying with extremity motion.[83,84] Because of the depth and variation in position, ultrasound guidance is useful for proximal sciatic nerve blocks in both adults and children.[85]

For procedures above the knee, the parasacral sciatic nerve block can provide an advantage over more distal approaches because the block of both the sciatic and posterior femoral cutaneous nerves is possible.[86-89] Alternatively, the posterior femoral cutaneous nerve can be blocked separately using ultrasound guidance.[90] The subgluteal approach to sciatic nerve block is useful when block of the hamstring muscles is indicated.[91] The anterior approach to sciatic nerve block is useful when the patient cannot be positioned for other approaches due to pain or leg traction.[92-94] These proximal approaches to sciatic nerve block may require multiple injections for rapid onset.[91] The

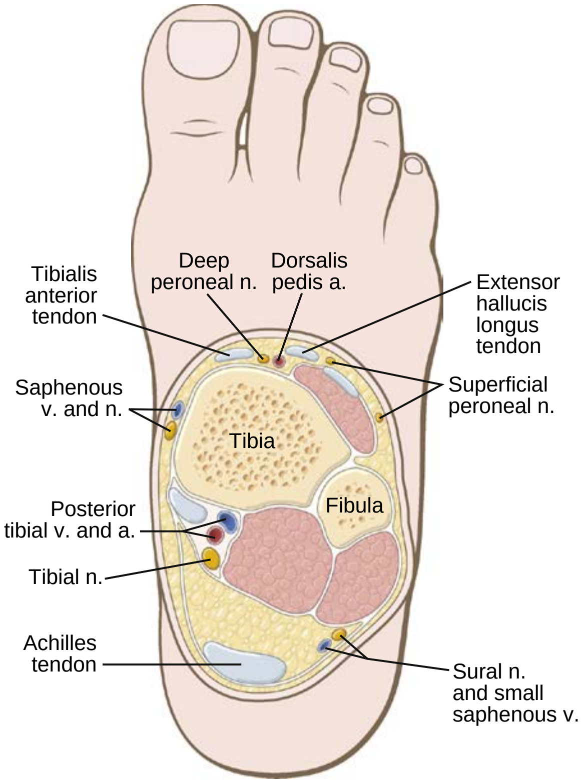

Fig. 46.32 Cross-sectional anatomy for an ankle block. An ankle block is performed by injecting local anesthetic solution at five separate nerve locations. The superficial peroneal nerve, sural nerve, and saphenous nerve are usually blocked by subcutaneous infiltration because they may have already branched as they cross the ankle joint. The tibial and deep peroneal nerves require deeper injection adjacent to the accompanying blood vessels (the posterior tibial and anterior tibial arteries, respectively). Because the block needle approaches the ankle from many angles, it is convenient to elevate the foot by supporting the calf. (Modified from Brown DL, Factor DA, eds. *Regional Anesthesia and Analgesia*. Philadelphia: WB Saunders; 1996.)

blood supply of the sciatic nerve in the gluteal region can be detected with ultrasound imaging, and this can help with nerve localization in some patients.[95]

NERVE BLOCKS AT THE ANKLE

Ankle blocks are relatively simple to perform and offer adequate anesthesia for surgical procedures of the foot. These blocks are traditionally performed at the level of the malleoli and guided by surface landmarks.

Four of the five individual nerves that can be blocked at the ankle to provide anesthesia of the foot are terminal branches of the sciatic nerve: the tibial, sural, superficial peroneal, and deep peroneal branches (Fig. 46.32). The sciatic nerve divides at or above the apex of the popliteal fossa to form the common peroneal and tibial nerves. The common peroneal nerve descends laterally around the neck of the fibula, where it divides into the superficial and deep peroneal nerves. The sural nerve forms in the leg from both tibial and common peroneal nerve contributions.

The saphenous nerve is the major descending sensory branch of the femoral nerve. The territory of this nerve is the medial leg and can extend as far as the base of the great toe and is included as part of the ankle block.[96]

Tibial Nerve Technique

The tibial nerve can be blocked with the patient in either the prone or the supine positions. The posterior tibial artery is palpated, and a 25-gauge, 3-cm needle is inserted posterolateral to the artery at the level of the medial malleolus (Fig. 46.33A and B). A paresthesia is often elicited; however, it is not necessary for a successful block. If a paresthesia is obtained, 3 to 5 mL of local anesthetic should be injected. Otherwise, 7 to 10 mL of local anesthetic should be injected as the needle is slowly withdrawn from the posterior aspect of the tibia. Blockade of the tibial nerve provides anesthesia of the heel, plantar portion of the toes, and the sole of the foot, as well as some motor branches in the same area. Ultrasound imaging of the tibial nerve can shorten onset time (Fig. 46.34).[97]

Sural Nerve Technique. The sural nerve is located superficially between the lateral malleolus and the Achilles tendon. A 25-gauge, 3-cm needle is inserted lateral to the tendon and is directed toward the malleolus as 5 to 10 mL of solution is injected subcutaneously (see Figs. 46.33 and 46.35). This block provides anesthesia of the lateral foot and the lateral aspects of the proximal sole of the foot.

Deep Peroneal, Superficial Peroneal, and Saphenous Nerve Techniques. The deep peroneal, superficial peroneal, and saphenous nerves can be blocked through a single needle entry site (see Fig. 46.35). A line is drawn across the dorsum of the foot connecting the malleoli. The extensor hallucis longus tendon is identified by having the patient dorsiflex the big toe. The anterior tibial artery lies between this structure and the tendon of the extensor digitorum longus muscle and is palpable at this level. A skin wheal is raised just lateral to the arterial pulsation between the two tendons on the intermalleolar line. A 25-gauge, 3-cm needle is advanced perpendicular to the skin entry site, and 3 to 5 mL of local anesthetic is injected deep to the extensor retinaculum to block the deep peroneal nerve. This technique anesthetizes the skin between the first and second toes and the short extensors of the toes.

The needle is directed laterally through the same skin wheal while injecting 3 to 5 mL of local anesthetic subcutaneously, blocking the superficial peroneal nerve and resulting in anesthesia of the dorsum of the foot, excluding the first interdigital cleft. The same maneuver can be performed in the medial direction, thereby anesthetizing the saphenous nerve, a terminal branch of the femoral nerve that supplies a strip along the medial aspect of the foot.

Side Effects and Complications

Multiple injections are required for this procedure, which can result in discomfort for the patient. Persistent paresthesias can occur, but they are generally self-limited. The presence of edema or induration in the area of the ankle block can make palpation of landmarks difficult. When this pathology is present, a more proximal block is usually performed (e.g., popliteal and saphenous nerves blocks in the distal thigh). Intravascular injection is possible but unlikely if aspiration for blood is negative.

INTRAVENOUS REGIONAL ANESTHESIA (OR BIER BLOCK)

Introduction and Clinical Applications

Intravenous regional blocks were first described in 1908 by the German surgeon, August Bier. The Bier block has multiple advantages, including ease of administration, rapid onset and recovery, muscular relaxation, and controllable duration of anesthesia. It is an excellent technique for short (<60 minutes) surgical procedures. Bier blocks are also used in the management of complex regional pain syndromes (for further details on intravenous regional analgesia in pain syndromes, see Chapter 51). Most commonly IVRA is used for upper extremity procedures such as excision of soft tissue masses or carpal tunnel release. Lower extremity blocks are also possible.

Technique (Upper Extremity)

With this technique blood is replaced with local anesthetic using a tourniquet to isolate the extremity from the central circulation. The duration of surgical anesthesia and analgesia for Bier block is essentially the time of tourniquet inflation. Contraindications to Bier block are the same as contraindications to tourniquet placement (limb ischemia, infection).

Prerequisites

Place a thin intravenous catheter (20 or 22 gauge) in the operative extremity (to reduce the amount of bleeding when the catheter is removed). Use only a minimal amount of dressing to secure the catheter. The intravenous catheter is usually placed distal or near the surgical site (although it is not clear if this influences block quality). If intravenous access is difficult, the procedure may need to be aborted.

Importantly, the patient should also have an intravenous cannula in the nonoperative upper extremity for administration of fluids and other drugs. If antibiotics are indicated they should be administered before the block (to allow these drugs to effectively reach the surgical site before tourniquet inflation). Lipid emulsion should be immediately available in the event that local anesthetic systemic toxicity occurs (see Chapter 29 for more details).

Extremity Exsanguination and Tourniquet Inflation

Raise the extremity above the level of the heart prior to exsanguination with an Esmarch bandage. This will passively drain venous blood from the extremity over one to two minutes (this can be done during the timeout). Stretch and wrap an Esmarch bandage around the extremity from distal to proximal in a spiral overlapping fashion, continuing until the cuff of the tourniquet is covered.

Following exsanguination with an Esmarch bandage, the tourniquet is typically inflated to 250 mm Hg or 100 mm Hg above systolic blood pressure. Therefore it is important that the patient be normotensive (systolic blood pressure 150 mm Hg or less) during the period of tourniquet inflation. If necessary, sedation or antihypertensive medications may be given. Another alternative is to increase the tourniquet inflation pressure to 275 mm Hg for brief tourniquet runs (usually <60 minutes for Bier blocks). For these reasons, it is important that blood pressure be carefully monitored and controlled during intravenous regional anesthesia. Both the surgical conditions and block quality are highly dependent on the exsanguination of the extremity.

Use of a single, wide cuff allows use of smaller inflation pressures during intravenous regional anesthesia. The postulated advantage is that the smaller pressures will decrease the incidence of neurologic complications related to high inflation pressures with the narrow double cuffs.[98]

Preservative free 2-chloroprocaine 0.5%, lidocaine 0.5%, or prilocaine 0.5% can be used for intravenous regional anesthesia (plain solution, without epinephrine).[99-101] For upper extremity anesthesia, an arm (about 0.6 mL/kg, maximum 50 mL) or forearm (about 0.4 mL/kg, maximum 25 mL) tourniquet can be used, depending on the surgical site.[102] Bupivacaine is not recommended for intravenous regional anesthesia because cases of severe local anesthetic toxicity have been reported.[103] However, dilute solutions of long-acting amides (0.125% levobupivacaine or 0.2% ropivacaine) have successfully been used to prolong sensory block and analgesia after tourniquet deflation.[104-106]

An additional temporary tourniquet (used for intravenous placement) can be placed immediately proximal to the surgical site while the first 10 or 20 mL of local anesthetic is injected via the catheter (the second tourniquet is then released). This will confine local anesthetic to the distal extremity and promote block onset.[107,108] Inject slowly so that venous pressures remain low. If the injection is at a distal site the leakage under the tourniquet will be reduced. The onset of anesthesia is usually within 5 to 10 minutes. After injection, the intravenous catheter is typically removed (although repeat injections using an indwelling catheter have been described).

Because the Bier block does not result in prolonged analgesia, long-acting local anesthetic should be infiltrated into the surgical field prior to tourniquet deflation. In this manner the onset of infiltrative analgesia matches the offset of the Bier block.

Tourniquet Deflation

The tourniquet can be safely released after 25 minutes, but the patient should be closely observed for local anesthetic toxicity for several minutes after the tourniquet release. Shorter tourniquet times (<25 minutes) are possible with 2-chloroprocaine because this local anesthetic is rapidly degraded by plasma esterases when blood re-enters the extremity upon tourniquet deflation. Rare cases of systemic toxicity from 2-chloroprocaine have been reported in patients with atypical esterases.[109]

Systemic plasma levels of local anesthetic will increase with venous return from the extremity following tourniquet deflation. This occurs when the tourniquet inflation pressure is less than venous levels (nearly 0 mm Hg). Cyclic deflation of the tourniquet at 10-second intervals for two or three cycles increases the time to peak arterial lidocaine levels, which may decrease potential toxicity.[110] It is recommended to not raise the extremity immediately after the tourniquet is removed, as this will promote venous return containing local anesthetic. Reinflate the tourniquet if any signs of systemic toxicity occur.

Comments

Double-Cuff Tourniquets. A double-cuff tourniquet can be used instead of a single-cuff tourniquet to extend the tourniquet tolerance time (Fig. 46.36). Both adjacent cuffs should have secure closures and reliable pressure gauges. After exsanguination of the arm, the proximal cuff is inflated to approximately 100 mm Hg greater than the systolic pressure, and absence of a radial pulse confirms adequate tourniquet pressure. When the patient complains of tourniquet pain, the distal tourniquet, which overlies anesthetized skin, is inflated, and the proximal tourniquet is released. However, if a long tourniquet time is anticipated it is usually best to choose other peripheral nerve block or provide a general anesthesia.

Additives and Adjuncts. Additives and adjuncts should be used with caution because prolonged exposure of these compounds to the venous endothelium during tourniquet

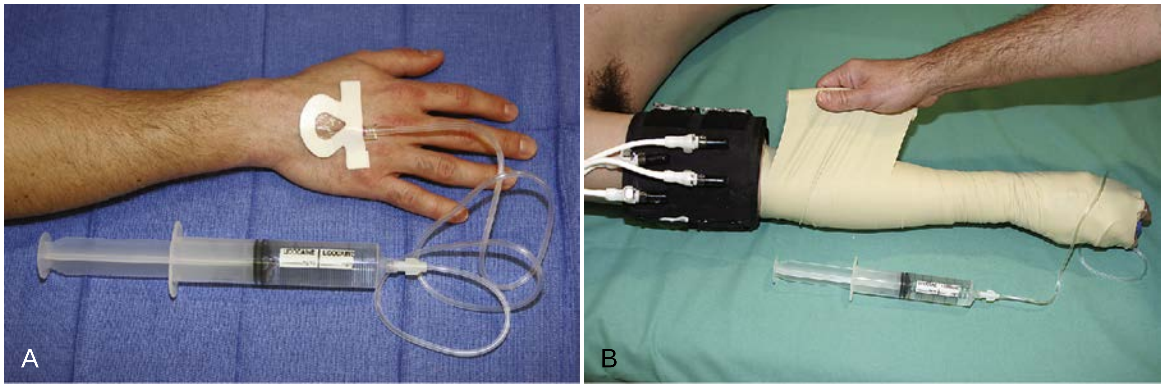

Fig. 46.36 (A) Placement and securing of a small intravenous catheter. (B) Exsanguination of the arm with an Esmarch bandage before inflation of the tourniquet and injection of the local anesthetic solution through the catheter. In this figure a double-cuff tourniquet is shown.

inflation may result in phlebitis (even if the compounds are considered safe for routine intravenous use).

Complications

Technical problems with this block include tourniquet discomfort, rapid resolution leading to postoperative pain, difficulty in providing a bloodless field, and the necessity of exsanguination in the case of a painful injury. Accidental or early deflation of the tourniquet or use of excessive doses of local anesthetics can result in systemic toxicity. Injection of the drug as distally as possible at a slow rate decreases blood levels and theoretically may increase safety. Nerve injury and compartment syndrome have been reported with long tourniquet times and high tourniquet inflation pressures. Hypertonic solutions can cause compartment syndrome and should never be used for intravenous regional anesthesia.[111]

The delivery rate accuracy of portable infusion pumps used for continuous regional analgesia. *Anesth Analg.* 2002;95:1331–1336.)

Continuous Catheter Techniques

The advantages cited for continuous nerve blockade include prolongation of surgical anesthesia, decreased risk of systemic toxicity because of lower incremental doses, postoperative pain relief, and sympathectomy. Catheter placement using over-needle and through-needle methods have been described. Advances in equipment technology, including the development of stimulating needles and catheters and portable pumps allowing local anesthetic infusion after hospital dismissal, have increased the success rate and popularity of continuous peripheral blockade (Fig. 46.37). Although concern regarding accurate catheter placement and maintenance still exists, the use of stimulating catheters and radiographic confirmation may further improve the functionality. Ultrasound guidance appears to produce more consistent times for catheter placement.[112] Overall, continuous peripheral nerve block provides superior analgesia compared with conventional opioid therapy. Minor technical problems such as catheter kinking, displacement or leakage, and bacterial colonization are frequent, with no adverse clinical consequences in the large majority of cases. Major neurologic and infectious adverse events are rare.

Methods of providing continuous brachial plexus anesthesia have been described since the 1940s. These methods frequently offer ingenious solutions for the placing and securing of the needle or catheter. This technique is especially applicable to patients with upper extremity or digit replantation, total shoulder or elbow arthroplasty, or reflex sympathetic dystrophies, for which prolonged pain relief and sympathectomy are advantageous.

Continuous lower extremity techniques were also described decades ago, but until recently have remained underused compared with continuous upper extremity and neuraxial approaches. Reliable, improved success rates and the risk of spinal hematoma after neuraxial techniques led clinicians to reconsider continuous lower extremity blocks. Contemporary applications for continuous psoas compartment, sciatic, femoral, adductor canal, and popliteal fossa blockade have been reported. Compared with conventional systemic and neuraxial analgesic methods, continuous lower extremity blocks provide superior analgesia with fewer side effects, improve perioperative outcomes, and accelerate hospital dismissal after major joint replacement.

TESTING THE CATHETER

Test injections of saline, local anesthetic, or air with real-time ultrasound imaging can be used to assess catheter tip function. The overall success rate of peripheral nerve catheter placement with ultrasound guidance is high, so the additional value of these subsequent tests is still being established.[113,114]

SECURING THE CATHETER

Catheter migration and dislodgement are clinically relevant issues. Catheter threading distances do not seem to correlate with the chance of dislodgement.[115] Excessively large threading distances (>5 cm) may result in catheter knotting. If ultrasound guidance is used for catheter placement, sterile dry gauze can be used to remove excess gel prior to securing the catheter. Skin adhesive applied to the catheter at the skin exit site may reduce catheter dislodgment, fluid leakage at the site, and chance of catheter related infection.[116,117] Application of skin adhesive at more than one site along the catheter may improve fixation.[118] A partial loop or coiling the catheter at the exit site will help reduce catheter dislodgement, and a variety of strain relief devices are now commercially available. Some practitioners elect to use tunnel catheters that are intended to remain in place for a prolonged period of time.

Choice of Local Anesthetic

The choice of local anesthetic for a peripheral nerve block depends to some extent on the duration of the surgical procedure, although other factors are also important (see Chapter 29). Prolonged blockade for up to 24 hours often occurs with long-acting local anesthetics such as bupivacaine or ropivacaine. Although this feature often results in superb postoperative pain relief, it may be undesirable in some patients because of the possible risk of nerve or tissue injury in a partially blocked limb. A short- or medium-acting local anesthetic, such as lidocaine or mepivacaine, may be more appropriate for surgical anesthesia. Whatever drug is chosen, the total dosage should be calculated for each patient and should be kept within safe limits (see Chapter 29 for details).

The highest concentrations of local anesthetic drugs are not appropriate for peripheral neural blockade; therefore 0.75% bupivacaine or ropivacaine, 2% lidocaine, 2% mepivacaine, and 3% 2-chloroprocaine are not recommended. The lowest concentrations of the same local anesthetics (i.e., 0.25% bupivacaine or ropivacaine and 0.5% mepivacaine or lidocaine) might not provide complete motor blockade.

Vasoconstrictors, usually epinephrine, can be added to the chosen local anesthetic to improve onset of action, to decrease drug uptake, and to prolong action. A concentration of 1:200,000 epinephrine is usually recommended. Ideally, the epinephrine should be added to the local anesthetic at the time the block is to be performed. Commercially prepared solutions with epinephrine have a lower pH than those in which it is freshly added, resulting in a higher percentage of ionized drug molecules. These ionized molecules do not readily cross the neural membrane, delaying the onset of drug action after injection. Epinephrine should not be added to the local anesthetic for blocks of the digits or penis because tissue ischemia can result. Various other additives, including steroids, clonidine, dexmedetomidine, opioids, and ketamine have been reported to enhance or prolong local anesthetic peripheral nerve blockade. Liposomal bupivacaine, which slowly releases this local anesthetic, is now FDA approved for some peripheral nerve blocks.

Box 46.3 Recommendations: Needle Tip Location, Choice of Local Anesthetic, and Nerve Localization Techniques

Needle Tip Location, Choice of Local Anesthetic, and Paresthesia

- Intrafascicular needle insertion and injection should be avoided because it can cause histological and/or functional nerve injury.

Nerve Localization Techniques

- There are no human data to support the superiority of one nerve localization technique over another with regard to reducing the likelihood of peripheral nerve injury.
- Peripheral Nerve Stimulation
  - Presence of an evoked motor response at a current of <0.5 (0.1 ms) indicates intimate needle-nerve relationship, needle-nerve contact, or an intraneural needle placement.
- Injection Pressure Monitoring
  - Animal data have linked high injection pressures to subsequent fascicular injury, but there are no human data that confirm or refute the effectiveness of injection pressure monitoring for limiting PNI.
- Ultrasound
  - Ultrasound can detect intraneural injection.
  - Current ultrasound technology does not have adequate resolution to discern between an interfascicular and intrafascicular injection.
  - Adequate images of needle-nerve interface are not consistently obtained by all operators and in all patients.

Modified from Neal JM, Barrington MJ, Brull R, et al. The second ASRA practice advisory on neurologic complications associated with regional anesthesia and pain medicine: executive summary 2015. *Reg Anesth Pain Med*. 2015;40(5):401–430. PMID:26288034.

Complications and Safety

Nerve injury is a recognized complication of peripheral regional techniques (Box 46.3). Risk factors contributing to neurologic deficit after regional anesthesia include neural ischemia, traumatic injury to the nerves during needle or catheter placement, and infection. However, postoperative neurologic injury because of pressure from improper patient positioning, tightly applied casts or surgical dressings, and surgical trauma is often attributed to the regional anesthetic. Patient factors such as body habitus or a preexisting neurologic dysfunction can also contribute.[119-121]

Although needle gauge, type (i.e., short vs. long bevel), and bevel configuration can influence the degree of nerve injury after peripheral nerve block, the findings are conflicting, and there are no confirmatory human studies. Theoretically, localization of neural structures with a nerve stimulator or ultrasound guidance would allow a high success rate without increasing the risk of neurologic complications, but this has not been established. Likewise, prolonged

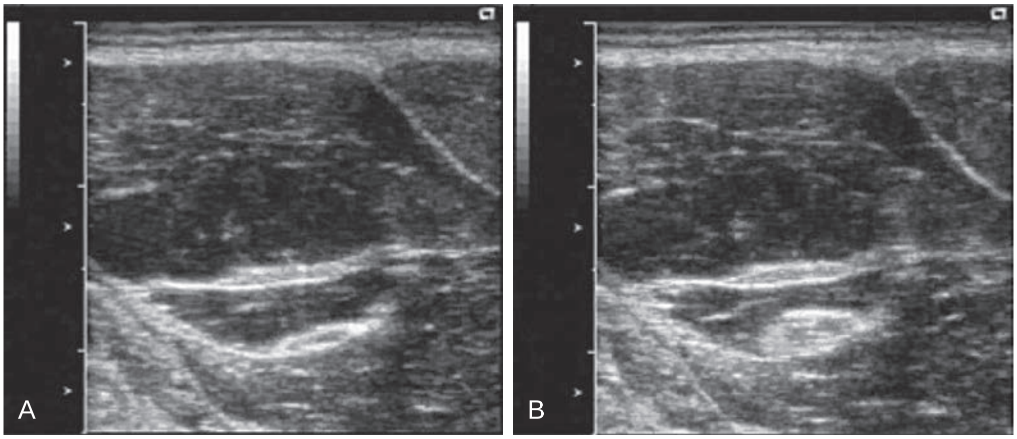

Fig. 46.38 Ultrasound image reveals intraneural injection. These sonograms were obtained in the axilla before (A) and after (B) injection in the musculocutaneous nerve. Nerve expansion is detected but with preservation of the overall integrity of the nerve borders. No paresthesias were observed during or after the procedure. Neurologic outcome was favorable after this low-volume, low-pressure injection.

exposure, high dose, or high concentrations of local anesthetic solutions can also result in permanent neurologic deficits. In laboratory models, the addition of epinephrine increases the neurotoxicity of local anesthetic solutions and decreases nerve blood flow; however, the clinical relevance of these findings in humans remains unclear. Nerve damage caused by traumatic needle placement, local anesthetic neurotoxicity, and neural ischemia during the performance of a regional anesthetic can worsen neurologic outcome in the presence of an additional patient factor or surgical injury.

Hemorrhagic complications have been described with nearly every peripheral technique and range from localized bruising and tenderness to severe hematomas or hemorrhagic complications. The placement of peripheral nerve blocks in patients with a coagulopathy should be performed with caution, especially in a deep, noncompressible site where an expanding hematoma could go unnoticed (e.g., lumbar plexus) or in a location where a hematoma could compress the airway (e.g., interscalene).[122]

Prevention of neurologic complications begins during the preoperative visit with a careful evaluation of the patient's medical history and appropriate preoperative discussion of the risks and benefits of the available anesthetic techniques. It is imperative that all preoperative neurologic deficits are documented to allow early diagnosis of new or worsening neurologic dysfunction postoperatively. Postoperative sensory or motor deficits must also be distinguished from residual (prolonged) local anesthetic effect. Imaging techniques, such as computed tomography and magnetic resonance imaging, are useful in identifying infectious processes and expanding hematomas. Although most neurologic complications resolve completely within several days or weeks, significant neural injuries necessitate neurologic consultation to document the degree of involvement and coordinate further workup. Neurophysiologic testing, such as nerve conduction studies, evoked potentials, and electromyography, are often useful in establishing a diagnosis and prognosis.

Infectious complications can be caused by exogenous (contaminated medication or equipment) or endogenous sources. Infection at the site of needle placement is an absolute contraindication to peripheral nerve blockade, although caution should be used in patients with nearby cellulitis or systemic blood infections (bacteremia or sepsis). Although bacterial colonization of peripheral nerve catheters is not uncommon, cellulitis, abscess, or bacteremia are extremely rare.[123-125]

Several large studies have established that severe systemic toxicity (seizures with or without cardiac arrest) occur on the order of 1:1000 for peripheral nerve blocks. Therefore practitioners of regional anesthesia must be familiar with the immediate detection and treatment of systemic local anesthetic toxicity. Systemic local anesthetic toxicity can occur immediately from an intravascular injection or it may be delayed because of rapid or excessive systemic absorption of local anesthetic. In addition to frequent aspiration during injection of local anesthetic, the addition of epinephrine can help alert the practitioner to potential intravascular injection. Attaching intravenous tubing to the needle allows immobility of the needle during injection. Typically, an assistant will aspirate with the syringe after each 5 mL injection of local anesthetic. Recent studies indicate that lipid emulsion rescue therapy improves success of resuscitation from cardiac arrest due to local anesthetic toxicity if given immediately after a local anesthetic overdose.[126-130]

For more details on treatment of local anesthesia toxicity, see Chapter 29.

Training

Interventional sonography is not without risks. Many studies have now demonstrated efficacy of ultrasound-guided regional blockade. Ultrasound has the potential to prevent and detect two important adverse events during peripheral nerve blocks: intravascular injection and intraneural injection of a local anesthetic.[131,132] The characteristic contrast from dissolved gas that is distributed within the vessel lumen can identify intravascular injection. The hallmark sign of intraneural injection is nerve expansion during injection (Fig. 46.38). Although ultrasound may have a profound impact on the safety of regional blockade,

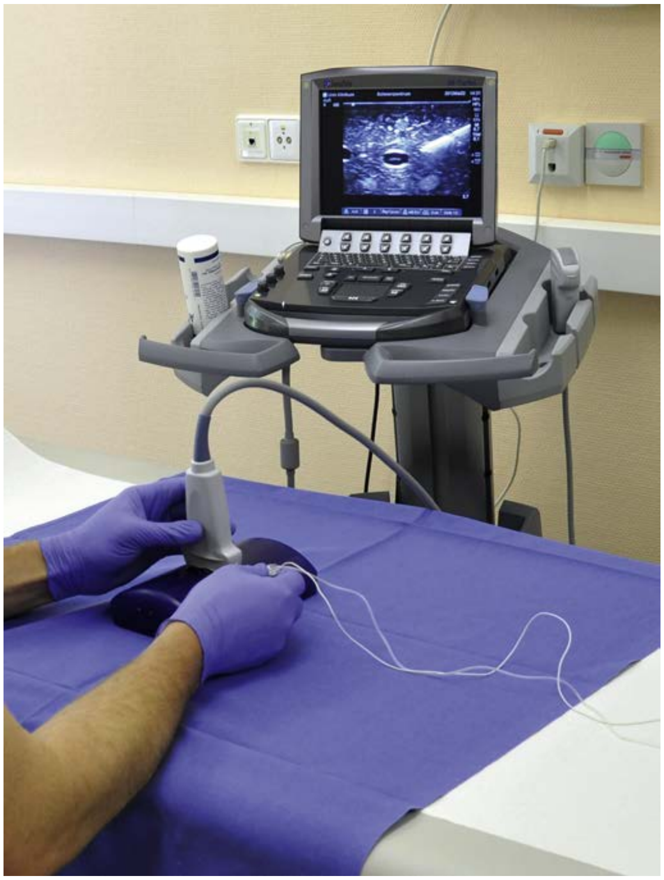

Fig. 46.39 Tissue equivalent phantom for training in ultrasound-guided interventions.

confirmatory studies of clinical practice are in progress. Many of these adverse events have only been recognized in retrospect by the review of recorded sonograms, which is a valuable training practice.

One of the original techniques developed for training novices in ultrasound-guided interventions was use of a tissue-equivalent phantom.[133] The phantom consisted of simulated tissue for needle placement practice (Fig. 46.39). To be realistic, the speed of sound must be similar as in soft tissue. In the first prototype, the phantom and container were clear; as a result, visual confirmation was possible. Several phantoms are now marketed for regional anesthesia purposes, and biologic tissue models that simulate nerve blocks have been developed.

A number of other effective teaching tools are being used. Cadavers have the advantage of realistic regional anatomic structures and can be used for simulated interventions.[134] The cost and use of specialized embalming methods that preserve nerve imaging and cadaver flexibility have limited this approach to a few specialized institutions. Most training studies have concluded that skills for ultrasound-guided procedures can be rapidly acquired.

One training study has identified common errors of novices while learning ultrasound-guided regional blocks.[135] These errors included advancing the needle when it was not visualized and unintentional probe movement. Novices often advance the needle even when it is not visualized, presumably because the natural inclination is to assume the needle has not reached the field of view. The potentially quality-compromising behaviors were largely eliminated by the end of the study period, which ranged from 66 to 114 blocks per training participant.

Summary and Conclusions

Peripheral nerve block techniques benefit the patient intraoperatively and postoperatively. Successfully mastering these techniques and applying them to the appropriate clinical situations add valuable options to the anesthetic care. Knowledge of regional anesthesia is also essential for the diagnosis and treatment of acute and chronic pain syndromes (see Chapters 51 and 82).

Ultrasound is a guidance tool that many people are electing to choose for regional anesthesia blocks. Once proficiency is established for a particular procedure, starting to use ultrasound for other interventional applications is relatively easy. Ultrasound imaging can prevent and detect critical events such as intravascular or intraneural injection that may improve safety during regional anesthesia procedures. However, if safety outcomes are to improve, then education and training play key roles in reducing these relatively uncommon adverse events.

Acknowledgments

The authors would like to thank Ram Jagannathan, MD, MBBS, for his help with imaging. Additionally, we would like to acknowledge Dr. Adam B. Collins for providing figure 46.36.

This chapter contains content from two chapters in the 8th edition text. The editors, publisher, and returning contributors, Drs. Sandra L. Kopp and Andrew T. Gray, would like to thank Drs. Terese T. Horlocker and Denise J. Wedel for their contribution in the prior edition of this work. It has served as a foundation for the current chapter.

Perioperative Fluid and Electrolyte Therapy

MARK R. EDWARDS and MICHAEL P.W. GROCOTT

KEY POINTS

- Intravenous fluid therapy is a core part of perioperative practice, with the potential to influence patient outcomes.
- Water makes up approximately 60% of total body weight, varying widely with age and body composition. The ratio between the water volume within the intracellular and functional extracellular compartments is approximately 2:1.
- The endothelial glycocalyx forms a protein-poor intravascular fluid layer at the vessel perimeter; it has been integrated into a revised version of the Starling equation and updated model of capillary fluid movement.
- Sodium is the dominant extracellular cation and is responsible for much of extracellular fluid osmolality; dysnatremia is typically associated with disturbed extracellular fluid volume.
- Potassium is the dominant intracellular cation with a key role in the maintenance of transmembrane potentials; dyskalemia may be accompanied by impaired function of excitable tissues.
- Calcium is a key intracellular second messenger with roles in neuromuscular function, cell division, and oxidative pathways.
- Magnesium has a diverse range of physiologic effects, underlined by the increasing range of therapeutic applications of supplemental magnesium in the perioperative setting.
- Acid-base balance is relevant to fluid therapy because fluids containing supraphysiologic levels of chloride may cause an iatrogenic acidosis; the clinical relevance of this acidosis is debated.
- Intravenous fluids have a range of physiologic effects and should be considered drugs with indications, dose ranges, cautions, and side effects.
- The physiologic insult of the perioperative period may lead to a wide variety of disturbances in fluid and electrolyte balance.
- Clinical evidence to guide perioperative fluid therapy is lacking in many areas and cannot be directly extrapolated from general critical care trials.
- A balance must be found between inadequate fluid administration—allowing tissue hypoperfusion—and the adverse effects of excess intravenous fluids and toxicities related to fluid constituents.
- Goal-directed fluid therapy (GDT) may help in finding this balance for an individual patient in the perioperative setting, with evidence of reduced postoperative morbidity supporting its use in many surgical settings.
- No clear consensus exists on which intravenously administered fluid is associated with the best clinical outcomes in the perioperative setting. Comparisons of "balanced" with "unbalanced" and "crystalloid" with "colloid" fluids are being studied in many clinical settings; definitive conclusions are often lacking.
- The approach to fluid and electrolyte management may need adapting to numerous patient and surgical factors.

The administration of intravenous (IV) fluid is a core expertise for anesthesia providers and an area in which we have an important role in advising clinical colleagues. Alongside the traditional triad of maintenance of unconsciousness, pain relief, and neuromuscular relaxation, IV fluid therapy is a core element of the perioperative practice of anesthesia. The aims of perioperative fluid administration should be to avoid dehydration, maintain an effective circulating volume, and prevent inadequate tissue perfusion during a period when the patient is unable to achieve these goals through normal oral fluid intake.

Knowledge of the clinical effects of different fluids has increased substantially in recent years. The choice of fluid type in a variety of clinical situations can be rationally guided by an understanding of the physicochemical and biologic properties of the various crystalloid and colloid solutions available in combination with the available clinical trial data. Each clinical decision about fluid therapy has two key elements: which fluid to use and how much fluid to give. Recently, several clinical studies have changed our concepts regarding both these questions. However, we should be cautious about overinterpreting data from nonperioperative contexts. Despite recent high-quality "mega-trials" involving thousands of critically ill patients, key questions remain unresolved in the perioperative setting. Goal-directed fluid therapy (GDT) is a good example of an intervention that is effective in the perioperative phase, but ineffective in established critical illness, and this should alert us to other possible similar distinctions. This chapter will review the physiology and pharmacology of IV fluid therapy in humans and discuss the impact of fluid and electrolyte management and alternative approaches on clinical outcomes.

Physiology

FLUID COMPARTMENTS

Water makes up approximately 60% of total body weight in the average adult, varying with age, gender, and body composition. Adipose tissue contains little water compared with other tissues, leading to marked variability in total body water (TBW) proportion between lean (75%) and obese (45%) individuals. Variation in adipose tissue also contributes to differences in TBW between adult males and females; these differences are reduced in old age as adipose tissue is reduced. The variations in body composition with age lead to a wide variation in TBW (Table 47.1). TBW is divided between anatomic and functional fluid compartments within the body, with the major division between intracellular fluid (ICF) and extracellular fluid (ECF). The size of these compartments and their widely differing composition are shown in Fig. 47.1 and Table 47.2. The ECF can be subdivided into the following compartments:

- Interstitial fluid (ISF): Lymphatic fluid and protein-poor fluid occupying cell spaces.
- Intravascular fluid: Plasma volume, including a proportion contained within the subglycocalyx (see later discussion).
- Transcellular fluid: Includes gastrointestinal (GI) tract fluid, bile, urine, cerebrospinal fluid, aqueous humor, joint fluid, and pleural, peritoneal, and pericardial fluid. These are functionally important fluids of widely varying composition contained within epithelial-lined spaces and regulated by active cellular transport (Table 47.3).
- Water in bone and dense connective tissue: Constitutes a substantial proportion of TBW but not part of the *functional* ECF because of slow kinetics of water distribution between this and other compartments.[1]

Total *blood* volume comprises extracellular (plasma and subglycocalyx compartments) and intracellular (blood cells) elements. With the nonfunctional ECF compartment (bone and connective tissue) excluded, the ratio between ICF and functional ECF is approximately 2:1 (ICF 55% of body weight to ECF 27.5% of body weight).

PHYSICOCHEMICAL LAWS GOVERNING FLUID AND ELECTROLYTE MOVEMENT

The movement of water and solutes is governed by a variety of physicochemical and biologic processes, discussed in the following section.

Diffusion

Diffusion is the process by which solute particles fill the available solvent volume by motion from areas of high to low concentration. The speed of this equilibration is proportional to the square of the diffusion distance.

Diffusion also may occur across permeable membranes, according to Fick's law of diffusion:[1]

$$J = -DA\left(\frac{\Delta c}{\Delta x}\right)$$

where J is the net rate of diffusion, D is the diffusion coefficient, A is the cross-sectional area available for diffusion, and $\Delta c/\Delta x$ is the concentration (chemical) gradient.

Diffusion may also be driven by the tendency of charged solutes to move down electrical gradients.

Osmosis

If a semipermeable membrane (one that is permeable to water but not a solute) separates pure water from water in which solute is dissolved, water molecules will diffuse across the membrane into the region of higher solute concentration. The hydrostatic pressure required to resist the movement of solvent molecules in this way is osmotic pressure. This is one of the fundamental colligative properties of a solution—that is, it depends on the number rather than the type of osmotically active particles in a solution, which may be complete molecules or dissociated ions.

Osmotic pressure in an ideal solution is affected by temperature and volume[2]:

$$P = \frac{nRT}{V}$$

TABLE 47.1 Age-Related Variation in Total Body Water and Extracellular Fluid as Percent of Body Weight (MULTIPLY by 10 for mL/kg)

Age	TBW (%)	ECF (%)	Blood Volume (%)
Neonate	80	45	9
6 months	70	35	
1 year	60	28	
5 years	65	25	8
Young adult (male)	60	22	7
Young adult (female)	50	20	7
Elderly	50	20	

In pregnancy, blood and plasma volumes increase by 45% and 50%, respectively, by term.

ECF, Extracellular fluid; *TBW*, total body water.

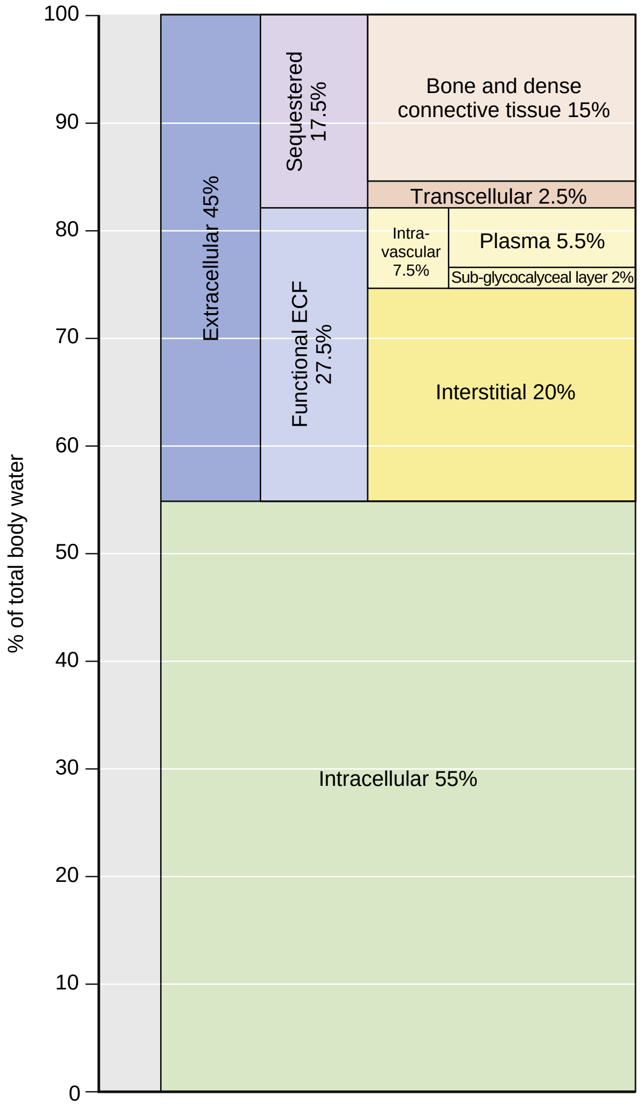

Fig. 47.1 Distribution of total body water between fluid compartments. "Sequestered" extracellular fluid *(ECF)* refers to water associated with bone and dense connective tissue or within the transcellular compartment and therefore not immediately available for equilibration with the other fluid compartments.

TABLE 47.2 Composition of Intracellular and Extracellular Fluid Compartments (in mOsm/L Water)

		EXTRACELLULAR	
	Intracellular	**Intravascular**	**Interstitial**
CATIONS			
Na^+	10	142	145
K^+	157	4	4
Ca^{2+}	0.5*	2.5	2.5
Mg^{2+}	20	0.8	0.7
ANIONS			
Cl^-	10	103	117
HCO_3^-	7	25	27
$HPO_4^{2-}/H_2PO_4^-$	11	2	2
SO_4^{2-}	1	0.5	0.5
Organic acids		6	6
Protein	4	1.2	0.2

Total intracellular Ca^{2+} concentration may be as high as extracellular levels; however, this is largely sequestered or buffered, such that the cytoplasmic ionized Ca^{2+} concentration is approximately 1000 times lower than extracellular fluid (0.3-2.6 μEq/L). The intracellular content of anions such as PO_4^{3-} has been difficult to establish for similar reasons.

Philadelphia: WB Saunders; 2010:285–300.

where *P* is the osmotic pressure, n is the number of particles, *R* is the gas constant, *T* the absolute temperature, and *V* the volume. The number of particles *(n)* can be calculated by multiplying (mass of solute/molecular weight of solute) by the number of particles into which the solute dissociates. However, body fluids are not ideal solutions, because interionic interactions reduce the number of particles free to exert an osmotic effect. The total osmotic pressure of plasma is approximately 5545 mm Hg.

Osmolality

Molality is the number of moles (each containing 6×10^{23} particles of *a specific substance*) present in 1 kg of solvent. Osmolality may be used to describe solutions containing many different types of particles and is the number of osmoles (each containing 6×10^{23} of *any type of particle present*) present in 1 kg of solvent. Normal body osmolality is 285 to 290 mOsm/kg and is the same in intracellular and extracellular compartments because of the free movement of water between compartments that consequently prevents the development of any osmotic gradients. The largest contribution to plasma osmolality is made by sodium and its related anions chloride and bicarbonate.

It can be estimated by[3]:

$$\text{Serum osmolality} = (2 \times \text{Na}) + (\text{glucose}/18) + (\text{urea}/2.8)$$

where Na is the serum sodium concentration (mEq/L), glucose is the serum glucose concentration (mg/dL), urea is the blood urea nitrogen concentration (mg/dL), and the (2 × Na) component reflects both Na and its associated anions (predominantly Cl^- and HCO_3^-). Alternatively, osmolality can be measured by depression of plasma freezing point.

Osmolarity is the number of osmoles of solute per liter of solution; unlike osmolality, this may be affected by temperature changes as a result of the volume-expanding effect of increasing temperature.

Tonicity

This is the *effective osmolality* of a solution with respect to a particular semipermeable membrane and takes into account solutes that do not exert an in vivo osmotic effect. For example, Na^+ and Cl^- do not cross cell membranes freely and therefore exert an effective osmotic force across these membranes, whereas urea freely diffuses across cell

TABLE 47.3 Composition of Transcellular Fluids (mEq/L Unless Stated)

	Daily Volume (L)	Cations				Anions		pH
Fluid		Na^+	K^+	Ca^{2+}	Mg^{2+}	Cl^-	HCO_3^-	
Gastrointestinal tract								
Saliva	1-1.5	30-90	20-40	2.5	0.6	15-35	10-40	6-7
Gastric	1.5-2.5	20-60	10-20			20-160	0	1-3.5
Bile	0.7-1.2	130-150	5-12	10-50		25-100	10-45	7-8
Pancreatic	1-1.5	125-150	5-10			30-110	40-115	8-8.3
Small bowel (concentrations from proximal to distal)	1.8	140-125	5-9			110-60	100-75	7-8
Large bowel	0.2 (lost in feces)	20-40	30-90			0-15	40	7-8
Sweat	0.1-0.5	45-60	5-10			45-60	0	5.2

membranes and therefore does not exert an osmotic effect here. Similarly, glucose is normally taken into cells by insulin-stimulated facilitated diffusion, so it is an ineffective osmole. Tonicity is important in determining in vivo distribution of fluids across a cell membrane and is sensed by the hypothalamic osmoreceptors. It can be estimated by subtracting urea and glucose concentrations from measured osmolality.

Oncotic Pressure

Oncotic pressure is the component of total osmotic pressure that is due to the colloids, that is, large molecular-weight particles, predominantly proteins (albumin, globulins, fibrinogen). Of the total plasma osmotic pressure of 5545 mm Hg, 25 to 28 mm Hg is due to plasma oncotic pressure. The negative charge on proteins has the net effect of retaining a small excess of Na^+ ions within the plasma (the Gibbs-Donnan effect), which effectively increases the oncotic pressure above what would be predicted by calculations based purely on protein concentration. As the most abundant plasma protein, albumin is responsible for 65% to 75% of plasma oncotic pressure.

FLUID COMPARTMENT BARRIERS AND DISTRIBUTION

The volume and composition of each fluid compartment depends on the barriers separating it from neighboring compartments.

Cell Membrane

The cell membrane separates the intracellular and extracellular compartments and as a lipid bilayer is impermeable to large hydrophilic molecules and charged particles such as free ions. Other than by passive diffusion of certain molecules, solutes may cross cell membranes in several ways.

Carrier Proteins

Primary active transport. Solute transport against a concentration gradient requires energy and is therefore directly coupled to adenosine triphosphate (ATP) hydrolysis—for example, by Na^+/K^+–adenosine triphosphatases (ATPases). This is the fundamental mechanism by which ionic concentration gradients are maintained, which in turn drive a variety of biologic processes, including water and solute movement and electrical impulse transmission in excitable tissues.

Secondary active transport. The process of secondary active transport uses concentration gradients set up by ATPases to transport a solute driven by an ion moving down its concentration gradient, typically Na^+. This process is termed cotransport when the solute is also moving down its concentration gradient or countertransport when the solute is being moved against its concentration gradient.

Solute Channels. The solute channels allow much faster transport of solutes than by ATPases or transmembrane diffusion. Examples include voltage-gated Na^+ channels and the glucose transporter GLUT1, which when inserted into the plasma membrane allows glucose to travel down its concentration gradient. This process is termed *facilitated diffusion.*

Endocytosis and Exocytosis. The processes of endocytosis and exocytosis are involved in the transport of large proteins and polypeptides across cell membranes.

Vascular Endothelium

The barrier function of the vascular endothelium is particularly relevant perioperatively because of its key role in maintaining intravascular fluid volume. Surgical tissue trauma typically leads to loss of intravascular volume through surgical blood loss or inflammation-related shifts to other tissue compartments. The physiologic effect of IV fluid administered to overcome these losses and maintain adequate tissue oxygen delivery is highly dependent on

TABLE 47.4 Capillary Characteristics

Capillary Type	Site	Large Pores	Basement Membrane	Glycocalyx Layer	Notes on Function
Nonfenestrated (continuous) 	Muscle, connective tissue, lung, nervous tissue	None	Continuous	Continuous	Intercellular clefts are the main route for fluid filtration. These are partly occluded by junctional strands with multiple breaks. In the blood-brain barrier, these breaks are small (1 nm) and infrequent (zona occludens tight junctions), permitting passage of only the smallest non-lipid soluble molecules. In other tissues, the breaks are larger (5-8 nm) and more frequent (macula occludens loose junctions).
Fenestrated 	Endocrine, gut mucosa, choroid plexus, lymph nodes	Pores within endothelial cells with covering diaphragm 6-12 nm size	Continuous	Continuous	Fenestrations allow capillary reabsorption of fluid from ISF, in contrast to other capillary types.
	Glomeruli	Endothelial pore size up to 65 nm	Continuous	Discontinuous over pores, reducing *effective* pore size	Numerous pores allow large-volume filtration at the glomerulus. The effective pore size is reduced further to 6 nm by podocytes; thus, proteins not usually filtered.
Sinusoidal 	Liver, spleen, bone marrowd	Large intercellular gaps up to 120 nm	Discontinuous	No effective layer because of endothelial uptake of hyaluronic acid	Large fenestrations allow macromolecules (lipoproteins, chylomicrons) to pass between plasma and ISF; the result is no COP to oppose filtration, and the ISF in these tissues is effectively part of the plasma volume. Large volume filtration to the ISF here cannot be accommodated by tissue expansion because of fibrous capsules and is returned via lymphatics (e.g., liver lymph production accounts for 50% of total body lymph production)

fluid handling at the capillary level. Our understanding of this area has been refined by experimental physiologic models and techniques.

Capillary Structure. As shown in Table 47.4, the structure of capillaries varies depending on the underlying organ function. The most common capillary type is the nonfenestrated capillary, comprising continuous basement membrane and a single layer of endothelial cells joined by junctions that are punctuated by breaks. These intercellular clefts are the primary channel for transcapillary fluid flow. The intravascular aspect of the endothelial cells is covered by a continuous network of glycosaminoglycan (GAG) chains, including syndecan-1, hyaluronic acid, and glypican, associated with membrane-bound proteoglycans; and glycoproteins, together forming the endothelial glycocalyx layer (EGL). The EGL covers fenestrations and intercellular clefts and has a thickness of up to 1 μm. In addition to its functions in preventing platelet and leukocyte adhesion, it has emerged as an important semipermeable layer contributing to endothelial barrier function.[2] Water and electrolytes can move freely across the vascular endothelial barrier through the EGL and then intercellular clefts or through fenestrations in the more specialized capillaries. Proteins were previously thought to be excluded from the ISF at the level of endothelial cells; however, it now appears that this occurs at the level of the glycocalyx. The subglycocalyceal layer (SGL) therefore contains protein-poor fluid; slower protein transport into the ISF may occur across the endothelial cells by endocytosis and exocytosis and by transport through a small number of large pores, forming a gradient in protein concentration from SGL to ISF compartments. The volume of the SGL may be as much as 700 to 1000 mL; this volume therefore forms part of the intravascular volume and has an electrolyte composition in equilibrium with the plasma but a much lower protein concentration because of the effective exclusion of larger molecules by the glycocalyx.

Capillary Function. The movement of fluid across the capillary membrane was initially described by Starling and then further refined. A hydrostatic pressure gradient at the arteriolar end of the capillary, greater than the inward oncotic pressure gradient, leads to net filtration of water into the ISF. Much of this water was previously thought to be reabsorbed into the vascular space toward the venular end of the capillary, where the outward hydrostatic pressure is lower and the inward oncotic pressure gradient is increased by exclusion of proteins from the capillary filtrate by the capillary endothelium. The water not reabsorbed by the capillary is removed from the ISF by the lymphatics.

More recent experimental and modeling techniques have integrated the role of the glycocalyx into a revised Starling equation and updated model of capillary fluid movement:[4]

$$J_v = K_f([P_c - P_i] - \sigma[\pi_c - \pi_{sg}])$$

where J_v is the transcapillary flow, K_f is the filtration coefficient, P_c is capillary hydrostatic pressure, P_i is the interstitial hydrostatic pressure, σ is the reflection coefficient (the degree to which the tendency of a macromolecule to cross the endothelial barrier is resisted), π_c is the capillary oncotic pressure, and π_{sg} is the subglycocalyx oncotic pressure.

The key differences and their clinical relevance are as follows[3]:

- At steady state, continuous capillaries *do not* exhibit fluid reabsorption toward the venous end of the capillary (the "no-absorption" rule). However, overall measured capillary filtration (J_v) is much less than predicted by the Starling principle, consistent with the larger colloid oncotic pressure (COP) gradient between SGL and capillary (opposing filtration) than between ISF and capillary. The smaller volume of filtrate is returned to the circulation by lymphatics.
- Plasma-SGL COP difference, not plasma-*ISF* COP difference, affects J_v. However, the no-absorption rule means that artificially raising COP (e.g., by albumin infusion) may reduce J_v but will not lead to reabsorption of fluid from the ISF into the plasma.
- An exception to the no-absorption rule occurs in acutely subnormal capillary pressures; a transient period of autotransfusion may occur, limited to approximately 500 mL. If subnormal pressures persist beyond this, J_v will approach zero, but ongoing reabsorption does not occur. Infusion of colloid in this setting will expand plasma volume, whereas infusion of crystalloid will expand total *intravascular* volume (plasma and EGL); J_v will remain close to zero in both cases until capillary pressure rises to normal or supranormal levels.
- At supranormal capillary pressures, COP difference is maintained and J_v is proportional to the hydrostatic pressure difference. In this setting, colloid infusion will maintain plasma COP but raise capillary pressure further and increase J_v. Crystalloid infusion will also increase capillary pressure but reduce plasma COP and therefore increase J_v to a greater extent than colloids.

The revised EGL model of fluid distribution, including the proposal that the intravascular volume effects of crystalloids and colloids are partly dependent on the preexisting capillary pressures (context sensitivity), helps explain some of the apparently conflicting findings in clinical fluid research.

CRYSTALLOID VERSUS COLLOID INTRAVASCULAR VOLUME EFFECTS. Infused crystalloid has been thought to distribute evenly throughout the extracellular compartments as a result of capillary filtration (J_v), leaving approximately one fourth or one fifth of the original volume within the circulating blood volume, whereas colloids were presumed to initially remain largely within the intravascular volume. However, many studies of the effects of fluids on blood volume are based on red blood cell (RBC) dilution and changes in the hematocrit and do not account for the influence of the SGL volume, from which RBCs are excluded. Colloids are also excluded from the SGL; by remaining in the plasma volume, they will have a diluting effect on the hematocrit and appear to remain within the circulating volume. Crystalloids initially distribute throughout the plasma and SGL volumes. As a result, their RBC dilutional effects are less than those of colloids. This has previously been interpreted as crystalloid leaving the circulating compartment and entering the ISF; however, a proportion of the infused crystalloid will remain in the blood volume within the SGL. Furthermore, context sensitivity is responsible for the observation that clearance of crystalloid from its central compartment (the intravascular volume) is slower under anesthesia than in awake subjects.[4] It may also explain why the amount of crystalloid required to get intravascular volume effects similar to colloid is in the ratio 1.5:1 rather than the predicted 4:1.[5–7] The value of this ratio in the perioperative context is less clear and has been inferred from large clinical trials in critically ill patients. However, it is likely to be closer to the measured values in critical illness than the theoretic values traditionally used.

FAILURE TO REDUCE EDEMA BY INCREASING CAPILLARY COLLOID ONCOTIC PRESSURE. Hypoalbuminemia is well recognized as a marker of disease severity in critical illness. However, administering exogenous albumin or other colloids to increase capillary COP does not reduce peripheral or pulmonary edema, nor improve overall outcomes in sepsis. The no-absorption rule can provide a partial explanation, because even increasing COP gradient across the capillary wall by administration of albumin will not lead to reabsorption of fluid from edematous tissues. Again, previous studies showing apparent shifts of fluid from the interstitial to the intravascular compartment based on a reduced hematocrit after albumin infusion do not account for the potential role of compaction of the glycocalyx layer and transfer of fluid from the SGL to the plasma volume.

Finally, the importance of the endothelial glycocalyx is highlighted by studies showing that its degradation significantly impairs endothelial barrier function.[8] A range of physiologic insults may lead to glycocalyx injury and shedding, with the subsequent appearance of free heparin, chondroitin, and hyaluronic acid in the plasma. These include natriuretic peptides (which may be released in acute excessive increased intravascular volume),[9] hyperglycemia, and inflammatory mediators released during surgery, trauma, and sepsis, such as C-reactive protein, bradykinin, and tumor necrosis factor (TNF).[10] Glycocalyx degradation may make an important contribution to the already well-characterized endothelial dysfunction seen in inflammation, in which phenotypic changes occur in endothelial cells. Here, an increase in the number of large pores, and a reduction in interstitial hydrostatic pressure favor J_v, with an increase in edema in compliant tissues such as the lung, muscles, and loose connective tissue. Impaired glycocalyx function will further favor J_v and lead to endothelial platelet aggregation and leukocyte adhesion. Maintenance of glycocalyx integrity is therefore gaining interest as a therapeutic target in perioperative fluid management.[11]

PHYSIOLOGIC CONTROL OF OVERALL FLUID BALANCE

In health, 60% of daily water loss is through urinary excretion, although this proportion is less when sweating and insensible losses are increased. Integrated cardiovascular and renal neuroendocrine mechanisms attempt to maintain fluid volume homeostasis in response to perioperative challenges, such as reduced oral fluid intake, blood loss, and IV fluid administration.

TBW volume is controlled by a system of sensors, central control, and effectors. The sensors are (1) hypothalamic osmoreceptors that respond to changes in ECF tonicity, (2) low-pressure baroreceptors in the large veins and right atrium that sense central venous pressure (CVP), and (3) high-pressure baroreceptors in the carotid sinus and aortic arch that sense mean arterial pressure. The sensory inputs are integrated within the hypothalamus, which then triggers either increased water intake from thirst or increased water output via antidiuretic hormone (ADH, arginine vasopressin) secretion. Thirst and ADH release may be triggered by increased plasma tonicity, hypovolemia, hypotension, and angiotensin II. ADH release also may be stimulated by stress (including surgery and trauma) and certain drugs (e.g., barbiturates). Water intake does not usually depend on thirst because of social drinking behavior; thirst acts as a backup mechanism when the normal intake is inadequate. ADH, produced in the hypothalamus and released from the posterior pituitary, acts on the principal cells of the renal collecting ducts, which in the absence of ADH are relatively impermeable to water. ADH combines with the vasopressin 2 (V2) receptors on the basolateral membrane of the cells, triggering cyclic adenosine monophosphate (cAMP)-mediated insertion of aquaporin 2 water channels into the apical membrane. This results in water reabsorption down its osmotic gradient and formation of concentrated urine.

Acute Disturbances in Circulating Volume

Acute variation in the intravascular volume leads to compensatory mechanisms over minutes to hours in an attempt to correct the acute abnormality. The homeostatic processes occurring in response to rapid blood loss are aimed at minimizing the change in effective blood volume (venoconstriction and mobilization of venous reservoirs, limited autotransfusion from ISF to plasma, reduced urine production) and maintenance of cardiac output and arterial pressure (tachycardia, increased inotropy, and vasoconstriction). The sensor organs for the acute change are the low-pressure and high-pressure baroreceptors, and initial changes are mediated through increased sympathetic outflow. Renal vasoconstriction leads to a reduced volume of filtrate and activates the renin-angiotensin-aldosterone (RAA) axis. Renin is released from the juxtaglomerular cells and cleaves angiotensinogen to form angiotensin I, which is rapidly converted to angiotensin II. This induces further sympathetic activity, vasoconstriction, aldosterone release from the adrenal cortex, and hypothalamic ADH production. The overall result is increased renal salt and water retention, increased peripheral vascular resistance, and increased cardiac output. In the absence of ongoing loss, the delayed responses to major blood loss restore plasma volume within 12 to 72 hours, increase hepatic plasma protein synthesis, and restore RBC levels by erythropoiesis within 4 to 8 weeks.

Conversely, the rapid infusion of fluid to a normovolemic healthy adult leads to an initial rise in venous and arterial pressure and cardiac output. Several mechanisms act rapidly to bring these cardiovascular parameters toward normal, including pressure receptor-mediated venodilation and venous blood pooling and reduction in systemic vascular resistance. At a tissue level, autoregulatory responses lead to arteriolar vasoconstriction to maintain constant blood flow in the face of increased perfusion pressure. Multiple mechanisms then act to return circulating volume toward normal. A proportion of the infused fluid will be lost as a result of capillary filtration, particularly if the infused fluid reduces COP. Low-pressure baroreceptor stimulation leads to a decrease in pituitary ADH secretion, allowing diuresis, and atrial stretch leads to atrial natriuretic peptide (ANP) release, favoring natriuresis. Further ADH-independent renal mechanisms include glomerulotubular imbalance resulting from the marginal reduction in plasma COP; this rapidly increases the glomerular filtration rate (GFR) and reduces proximal tubule water and Na^+ reabsorption, increasing urine volume. Finally, increased arterial blood pressure promotes the excretion of excess water and salt (i.e., pressure natriuresis and pressure diuresis). This is the pressure-volume control mechanism, one of the key mechanisms for the long-term maintenance of normal blood volume. However, arterial blood pressure is only slowly restored by cardiovascular reflexes after acute hypervolemia. It may take several days for a 20 mL/kg dose of isotonic salt solution to be fully excreted. Excretion of excess Na^+ and water depends more on these passive processes and suppression of the RAA axis than on natriuretic peptide activity.[12] The contrast between this inefficiency and the rapid, effective mechanisms for dealing with reduced fluid volume and Na^+ content reflects the evolution of physiology in an environment with a paucity of salt and variable water availability; excess Na^+ intake is a feature of modern diets.

Long-Term Control of Circulating Intravascular Volume

The Guyton-Coleman model is the archetypal representation of the circulation. Despite calls to refine the mathematic modeling of the long-term control of arterial blood pressure, it remains the most widely used model to explain the chronic control of blood volume and arterial pressure.[13–15] In health, short-term variations in blood volume are very small and the cardiovascular system behaves as a closed system with arterial pressure a product of peripheral resistance, vascular compliance, and the Starling curve.[16] In the chronic setting or in acute alterations in blood volume, as described earlier, the circulating volume will vary and equality of input and output must be restored to avoid chronic fluid retention or dehydration; thus, the circulation acts as an open system. The kidneys are the primary organ regulating this equilibrium, largely through pressure natriuresis and diuresis. Indeed, in the chronic setting, arterial pressure subserves the renal requirement to excrete ingested Na^+ and water rather than simply being a product of cardiac output, vascular compliance, and resistance. A recent interpretation integrates the Guyton-Coleman model with experimental observations (Fig. 47.2).[16] In health, the pressure-natriuresis curve is relatively flat, and excess intake of salt and water can be excreted without long-term rises in circulating volume or blood pressure. In many models of chronic hypertension, the renal excretion mechanism is reset such that natriuresis occurs only at higher arterial pressures and excessive exogenous water and salt results in higher blood pressure.

ELECTROLYTE PHYSIOLOGY

Sodium Physiology

Na^+ is the dominant extracellular cation, and along with its associated anions accounts for nearly all the osmotically active solute in plasma and interstitial fluid. The relatively free movement of water throughout the fluid compartments means that Na^+ is therefore the prime determinant of ECF volume. Total body Na^+ content is approximately 4000 mmol, of which only 10% is intracellular. The concentration gradient between the intracellular and extracellular compartments (ratio 1:15) is maintained by ATPases and is vital for the function of excitable tissues, including action potentials and membrane potential, and for the handling of renal solute.

Na^+ intake is typically far in excess of minimum daily requirements, which are 2 to 3 mEq/kg/day at birth and decrease to 1 to 1.5 mEq/kg/day in adulthood.[17,18] Na^+ is actively absorbed from the small intestine and colon under the influence of aldosterone and the presence of glucose in the gut lumen. Loss is predominantly by the renal route, with minor contributions from feces, sweat, and skin (10 mEq/day each). Na^+ is freely filtered at the glomerulus, of which 99.5% is reabsorbed, mainly at the proximal convoluted tubule. Serum Na^+ concentrations are maintained within a tight range (138-142 mEq/L) despite wide variation in water intake by the systems involved in the control of circulating volume outlined previously:

- hypothalamic osmoreceptor: ADH release
- atrial volume sensing: ANP release
- juxtaglomerular apparatus (renal arteriolar baroreceptor and filtrate NaCl content sensing): RAA activation

The excretion of total body excess Na^+ relies on inefficient passive mechanisms, particularly the pressure-volume effect. Long-term ingestion of excess salt combined with low potassium ingestion contributes to hypertension, a condition not seen in populations with daily salt intake less than 50 mmol. The mechanism involves renal salt retention and initial extracellular volume expansion (later mitigated by pressure natriuresis), with release of an endogenous digitalis-like factor and stimulation of renal Na^+ pumps, furthering renal Na^+ retention. Low K^+ combined with the chronic action of digitalis-like factor inhibits vascular smooth muscle cell Na^+/K^+ ATPases, resulting in excess intracellular Na^+ content and reduced intracellular K^+, smooth muscle contraction, and increased peripheral vascular resistance.[19]

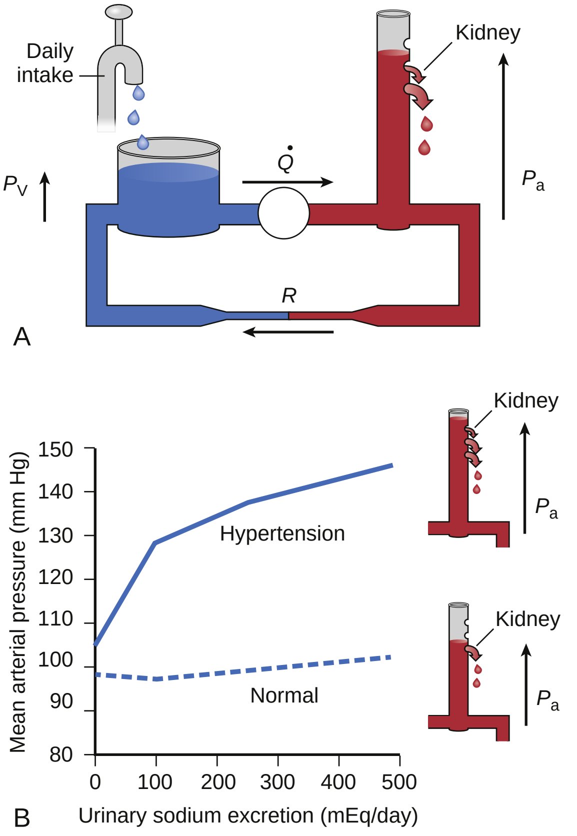

Fig. 47.2 Long-term control of blood volume in health and hypertension. (A) Representation of the open circulation model. In the chronic setting, arterial pressure *(P_a)* depends on daily water and sodium intake *(dripping tap)* and the renal pressure-natriuresis relationship *(represented by the height of the holes in the arterial column)* rather than cardiac output $(\dot{Q})$ and peripheral resistance *(R)*. (B) Experimental models of hypertension (e.g., long-term angiotensin II infusion) with controlled sodium intake (and therefore excretion) demonstrate a reset pressure-natriuresis curve in hypertension. This may be represented by kidney *holes* positioned further up the arterial column. Natriuresis occurs to a degree similar to that in normotension, so as to maintain a stable body water volume, but requires a higher arterial pressure to do so. P_V, Venous pressure. B, Data from Hall JE. The kidney, hypertension, and obesity. *Hypertension*. 2003;41:625.)

Potassium Physiology

K^+ is the dominant intracellular cation in the body, with a total body content of approximately 4000 mmol, 98% of which is intracellular, particularly in muscle, liver, and RBCs. The ratio of ICF to ECF K^+ balance is vital in the maintenance of cellular resting membrane potential, and K^+ therefore has a key role in the behavior of all excitable tissues. Daily requirements reflect age and growth, with more K^+ required at higher metabolic rates. Term infants require 2 to 3 mEq/kg/day and adults 1 to 1.5 mEq/kg/day. Nearly all ingested K^+ is absorbed by the intestine, and minimal amounts are excreted in feces. The acute and chronic handling of K^+ must therefore maintain a stable plasma K^+ concentration and resting membrane potential in the face of a daily K^+ intake of a similar magnitude to the entire ECF K^+ content. Transmembrane potentials particularly depend on K^+ permeability, with K^+ egress occurring through ion channels down its concentration gradient. This leaves behind intracellular anions, with a resultant negative transmembrane potential. The resting value of this potential is achieved when the tendency of K^+ to move extracellularly as a result of its concentration gradient is matched by the tendency of K^+ to move intracellularly because of the electrical gradient.

Acute K^+ distribution involves shifts in K^+ between the ECF and ICF, performed by ion transport systems under the influence of insulin, catecholamines, and ECF pH. The cell membrane Na^+/K^+ ATPase exports three Na^+ for every two K^+ imported and is the means by which the gradients of these ions are maintained. Insulin, released after ingestion of K^+-containing food, stimulates the Na^+/H^+ antiporter, increasing intracellular Na^+, which is then removed by Na^+/K^+ ATPase with the net cellular uptake of K^+. Conversely, in the presence of hypokalemia, skeletal muscle expression of Na^+/K^+ ATPase is reduced, allowing a "leak" of K^+ from the ICF to ECF.[20] Catecholamines activate β_2-adrenoceptors, which ultimately stimulate Na^+/K^+ ATPase activity, leading to increases in ICF K^+, a mechanism that counteracts the release of K^+ from muscle cells during exercise.[21] ECF pH also has a bearing on K^+ handling. The presence of mineral organic acids (where the acid anion is unable to diffuse into the cell) leads to increased cellular H^+ uptake in exchange for K^+ ions with consequent increases in ECF K^+. Organic acids (e.g., lactic acid and ketone bodies) are more able to diffuse across cellular membranes and H^+/K^+ exchange is much less. Hyperkalemia may be observed in the setting of organic acidemia resulting from alternative mechanisms, such as insulin deficiency and osmotic drag in diabetic ketoacidosis or a failure of ATP production for Na^+/K^+ ATPase in situations typified by anaerobic metabolism and lactic acidosis. Other factors that may influence ECF to ICF K^+ balance include aldosterone (which at high levels may induce intracellular K^+ shift, beyond its renal effects), hyperosmolar states (solvent drag of K^+ along with water efflux), and digoxin (inactivates Na^+/K^+ ATPase and may cause hyperkalemia).

Chronic K^+ distribution involves renal mechanisms. K^+ is freely filtered at the glomerulus, and undergoes extensive unregulated reabsorption along the proximal tubule, with only 10% to 15% reaching the distal nephron, where its reabsorption or secretion is tightly controlled. This occurs predominantly in two cell types found in the collecting ducts.

Principal Cells. The principal cells are able to secrete K^+ under the electrochemical gradients set up by basal Na^+/K^+ ATPases, which maintain low intracellular Na^+ concentrations (aiding Na^+ reabsorption from the tubule via Na^+ channels) and high intracellular K^+ concentrations (favoring K^+ secretion into the tubule via K^+ channels). Principal cell behavior is influenced by the following:

- Aldosterone, synthesized and released by the adrenal glands in response to raised K^+ concentrations. This mineralocorticoid increases the synthesis and activity of both basal Na^+/K^+ ATPases and luminal K^+ channels to drive urinary K^+ secretion.
- Tubular Na^+ delivery. Increased distal tubular Na^+ content leads to a steeper Na^+ concentration gradient and increased principal cell reabsorption of Na^+. To maintain electroneutrality of the tubular fluid, K^+ efflux into the tubule increases; this is partly responsible for the hypokalemia associated with diuretics that increase delivery of Na^+ to the cortical collecting ducts (thiazides and loop diuretics). In contrast, amiloride blocks the principal cell luminal Na^+ channel and therefore does not affect K^+ efflux here.

Intercalated Cells. In addition to basal Na^+/K^+ ATPases, these cells have luminal H^+/K^+ ATPases that excrete one hydrogen into the tubule for every K^+ reabsorbed. Low K^+ settings lead to up-regulation of this luminal antiporter, reabsorbing more K^+ at the expense of renal acid loss.

In addition to mechanisms involving aldosterone in a feedback loop, it is likely that feed-forward mechanisms also exist to rapidly modulate renal K^+ handling when K^+ is sensed in the GI system, even before plasma K^+ levels rise.[20]

Calcium Physiology

Beyond its role in bone structure, where 98% of body calcium (Ca^{2+}) is stored, Ca^{2+} is one of the body's most important intracellular second messengers, playing a key role in muscular contraction, neuromuscular transmission, cell division and movement, and oxidative pathways. Intracellular Ca^{2+} entry may have direct effects in cardiac and skeletal muscle contraction—for example, leading to neurotransmitter release or inducing further large-scale release of Ca^{2+} from intracellular stores (Ca^{2+}-induced Ca^{2+} release). A large ECF-to-ICF gradient of ionized Ca^{2+} is maintained by ATPases, and cytoplasmic free Ca^{2+} levels are kept low by pumping into the sarcoplasmic reticulum. Increases in cytoplasmic Ca^{2+} concentration occurring as a result of cellular energetic failure and impaired Ca^{2+} transport are a key mediator of cell death pathways.[22] Ca^{2+}also plays a key role in coagulation by linking coagulation factors to the negatively charged plasma membrane of activated platelets.

Homeostatic mechanisms maintain serum Ca^{2+} concentrations between 4.5 and 5 mEq/L (8.5-10.5 mg/dL), largely under the influence of vitamin D and parathyroid hormone (PTH). Ionized Ca^{2+} is sensed by the extracellular domain of a G-coupled receptor expressed on parathyroid cells (the Ca^{2+}/Mg^{2+}-sensing receptor), inhibiting PTH release.[23] When ionized Ca^{2+} levels decrease, PTH is rapidly released with the following actions:

- Stimulates osteoclast bone resorption, releasing Ca^{2+} into the ECF
- Stimulates distal tubule calcium reabsorption
- Stimulates the renal conversion of 25-(OH)-vitamin D to 1,25-$(OH)_2$-vitamin D (calcitriol, the most active vitamin D metabolite)

The manufacture of active vitamin D involves cholecalciferol formation in the skin during exposure to ultraviolet

TABLE 47.5 Physiologic Roles of Magnesium

System	Effect	Mechanism and Clinical Relevance
Neurologic	Reduction in pain transmission	NMDA antagonism. Mg^{2+} treatment provides effective perioperative analgesia.[254]
	Reduces neuromuscular transmission	Inhibition of neuronal Ca^{2+} influx reduces neuromuscular junction ACh release (and motor end-plate sensitivity to ACh). Hypermagnesemia potentiates the effects of neuromuscular blockade.
	Sympatholysis	Inhibition of neuronal Ca^{2+} influx reduces catecholamine release from adrenal medulla and adrenergic nerve endings. Pharmacologic use of Mg^{2+} in obtunding pressor response to intubation or during surgery for pheochromocytoma.
	Anticonvulsant	Mechanism may relate to NMDA antagonism or cerebral arteriolar vasodilation, possible mechanisms for its efficacy in eclampsia, in which vasospasm has been observed.[29]
	Cortical depression at high levels	
Cardiovascular	Vasodilation	Predominantly arteriolar, because of inhibition of Ca^{2+} influx-mediated vascular smooth muscle contraction. Mg^{2+} administration typically leads to a minor reflex increase in inotropy despite the direct action of Mg^{2+} on reducing cardiac contractility.[255]
	Antiarrhythmic effects	Mixed class IV (Ca^{2+} channel inhibition) and weak class I (Na^+ channel inhibition) effects. Increases atrioventricular nodal conduction time and refractory periods, suppresses accessory pathway transmission, and inhibits early and delayed afterdepolarizations. Clinical use is in supraventricular tachycardias, atrial fibrillation rate control and postoperative prophylaxis, and tachyarrhythmias associated with dyskalemia, digoxin, bupivacaine, or amitriptyline.[29]
	Improved myocardial O_2 supply-to-demand ratio	Coronary vasodilation in combination with reductions in heart rate and contractility; however, no clear evidence of benefit in the setting of acute myocardial infarction.
Respiratory	Bronchodilation	Smooth muscle relaxation. Pharmacologic use of Mg^{2+} is in acute bronchospasm.
Renal	Renal vasodilation and diuresis	Ca^{2+} antagonism-related smooth muscle relaxation
Immune	Antiinflammatory	Pharmacologic doses of magnesium sulfate reduce monocyte inflammatory cytokine production.[256]
	Adaptive immunity	Mg^{2+} is required as a second messenger during T-lymphocyte activation.[257]
Obstetric	Tocolysis	May be due to smooth muscle relaxation

ACh, Acetylcholine; *NMDA, N*-methyl-D-aspartate.

light, which then undergoes hepatic hydroxylation to 25-hydroxy-calciferol, then renal hydroxylation under the influence of PTH to 1,25-dihydroxycalciferol (calcitriol). As with PTH, this stimulates osteoclastic bone resorption and additionally stimulates absorption of Ca^{2+} from the GI tract.

Ca^{2+} homeostasis is interlinked with that of other anions. In particular, magnesium is also able to modulate PTH levels, and hypocalcemia and hypomagnesemia frequently coexist. The homeostasis of phosphate (PO_4^{3-}) is effectively the converse of Ca^{2+} (e.g., renal hydroxylation of vitamin D is inhibited by hyperphosphatemia), and in health the (calcium × phosphate) product is kept relatively stable. An increase in the (calcium × phosphate) product may be seen in advanced chronic kidney disease and is associated with ectopic bone deposition.

Approximately 50% of circulating Ca^{2+} is in the biologically active ionized form (the remaining 40% are bound to proteins, predominantly albumin and globulins, and 10% are complexed to anions such as HCO_3^-, citrate, sulfate, PO_4^{3-}, and lactate). Hypoalbuminemia decreases the total serum Ca^{2+} but has less effect on the biologically important ionized form. To calculate the corrected total Ca^{2+} concentration, 0.8 mg/dL is added per 1 g/dL decrease in albumin concentration below 4 g/dL. The degree of albumin-protein binding is affected by pH, with acidemia reducing protein binding and increasing the ionized fraction. Ionized Ca^{2+} rises by approximately 0.1 mEq/L per 0.1 decrease in pH.[26] Given the approximate nature of corrected total Ca^{2+}, biologically active ionized Ca^{2+} should be measured when possible. Specimens should ideally be taken without tourniquet (uncuffed), because local acidosis increases the ionized fraction.

Magnesium Physiology

Mg^{2+} has a diverse range of cellular actions, including modulation of ion channel activity and as an essential component of ATP production and hydrolysis. It is primarily an intracellular anion, although most is sequestered within organelles, bound to phospholipids, proteins, and nucleic acids. Free ionized Mg^{2+} levels within the cytoplasm and ECF are therefore low (0.8-1.2 mM), and chemical concentration gradients are much less than for other anions. Of total body Mg^{2+}, 50% is within bone, 20% within muscle, and the rest in liver, heart, and other tissues. Only 1% is within the ECF, and normal plasma levels may be maintained in the face of total body Mg^{2+} depletion. Within the plasma, total Mg^{2+} concentration is 1.5 to 2.1 mEq/L, of which approximately 25% is protein (mostly albumin) bound, 65% is in the biologically active ionized form, and the remainder is complexed to phosphates, citrates, and other anions.[27] Measurement of ionized Mg^{2+} can be performed, although correction is required for interference from Ca^{2+} ions.[28] The key roles of Mg^{2+} (Table 47.5) highlight its diverse range of clinical applications when administered exogenously and stem from the following three main cellular actions:

1. Energy metabolism: Mg^{2+} is required for ATP phosphorylation reactions, interacting with the outer two PO_4^{3-}

groups of ATP. Intracellular Mg^{2+} deficiency therefore impairs any enzyme systems using high-energy PO_4^{3-} bonds, such as glucose metabolism.[27]

2. Nucleotide and protein production: Mg^{2+} acts as a cofactor in every step of DNA transcription and replication and messenger RNA (mRNA) translation.
3. Ion transport: by supporting the activity of ion-pumping ATPases, Mg^{2+} helps maintain normal transmembrane electrochemical gradients, effectively stabilizing cell membranes and organelles. In addition, effects on ion *channels* underlie one of the core functions of Mg^{2+}, namely physiologic competitive antagonism of Ca^{2+}. This is mediated through inhibition of L-type Ca^{2+} channels and extracellular local modification of membrane potential, preventing the intracytoplasmic influx of Ca^{2+} from both the ECF and intracellular sarcoplasmic reticulum stores. Mg^{2+} also effectively antagonizes *N*-methyl-D-aspartate (NMDA) receptors within the central nervous system, reducing Ca^{2+} entry by specific ion channels. These effects result in inhibition of a diverse array of excitable tissue cellular actions, including neurotransmitter release, muscular contraction, cardiac pacemaker and action potential activity, and pain signal transmission.

Mg^{2+} is absorbed from the GI tract by a saturable transport system and passive diffusion, in quantities inversely proportional to the amount ingested. Excretion is via the GI tract (~60% of the ingested amount) and kidneys. Seventy-five percent is freely filtered at the glomerulus, and proximal tubule reabsorption is minimal, with 60% to 70% being reabsorbed at the thick ascending loop of Henle and 10% reabsorbed under regulation in the distal tubule. The regulation of total body Mg^{2+} levels by GI uptake and control of renal excretion is not under the control of a well-defined hormonal feedback loop. Although many factors can influence Mg^{2+} reabsorption (particularly PTH but also calcitonin, glucagon, acid-base balance, Ca^{2+} and K^+ levels), the main determinant is the plasma Mg^{2+} concentration, sensed by Ca^{2+}/Mg^{2+}-sensor receptors present on the basal aspect of thick ascending loop cells. Other influences may alter the intracellular-extracellular balance of magnesium distribution. Catecholamines, acting by both α- and β-adrenoreceptors, and glucagon lead to extrusion of magnesium from intracellular stores. Although experimental models have shown that adrenergic stimulation may increase serum Mg^{2+} concentrations, decreases in serum Mg^{2+} concentrations actually occur after stressors such as surgery, trauma, burns, and sepsis.[27,29] This may be due to a later phase of catecholamine-driven cellular uptake after the initial Mg^{2+} efflux.[30]

Phosphate Physiology

PO_4^{3-} is the most abundant intracellular anion and helps form some of the most important biologic molecules, including ATP, DNA, and RNA, membrane phospholipids, 2,3-diphosphoglycerate (2,3-DPG), and hydroxyapatite in bone. PO_4^{3-} is therefore required for energy metabolism, cellular signaling through phosphorylation reactions, cellular replication and protein synthesis, membrane integrity, and O_2 delivery. In addition, the PO_4^{3-} buffer system is one of the key intracellular buffers. Of total body phosphorus, 80% to 90% is stored in bone, with the remainder in the intracellular (soft tissues and erythrocytes) and extracellular fluid compartments.[31] Normal plasma inorganic phosphates are maintained at 3 to 5 mg/dL, and at normal pH, 80% exists in the divalent (HPO_4^{2-}) rather than monovalent ($H_2PO_4^-$) form. Plasma phosphates also include lipid phosphates and organic ester phosphates. Most intracellular PO_4^{3-} is organic.[18]

The typical daily intake of PO_4^{3-} (~1 g) outweighs metabolic requirements, yet 70% is absorbed, leading to postprandial increases in serum PO_4^{3-} levels that are rapidly dealt with by increased renal excretion. GI uptake occurs predominantly by paracellular diffusion and is unregulated unless PO_4^{3-} ingestion is reduced, when vitamin D and PTH-stimulated active transport intervene.[32,33] Plasma inorganic PO_4^{3-} is freely filtered at the glomerulus, 80% of which is reabsorbed in the proximal tubule and a smaller amount in the distal tubule. Proximal tubule reabsorption is via Na^+-dependent cotransporters, the expression and activity of which are under the influence of PTH and PO_4^{3-} intake.

The regulation of normal PO_4^{3-} levels is mediated primarily by the PTH and vitamin D systems. Low plasma PO_4^{3-} levels stimulate 1-hydroxylase activity, with the formation of active vitamin D (1,25-dihydroxycalciferol), which increases GI and renal PO_4^{3-} absorption. Conversely, PTH release (stimulated by reduced plasma Ca^{2+}) reduces renal PO_4^{3-} reabsorption. PO_4^{3-} plasma levels also may be reduced in the short term by cellular uptake in response to dopamine and adrenergic activity and alkalosis and intestinal factors (phosphatonins) released in response to increased intestinal luminal PO_4^{3-}.[31]

Chloride Physiology

As the second most abundant electrolyte in the extracellular compartment, chloride (Cl^-) has a key role in the maintenance of plasma osmolality, preservation of electrical neutrality, and acid-base status (explained by the Stewart model, see later discussion). Normal plasma values are 97 to 107 mEq/L; Cl^- is therefore responsible for nearly a third of plasma osmolality and two thirds of plasma negative charge.[34] Most Cl^- intake is derived from dietary NaCl, and the GI tract absorbs and secretes large amounts of Cl^-, primarily as gastric hydrochloric acid, but also throughout the intestinal lumen. This cellular Cl^- secretion leads to paracellular movement of Na^+ into the lumen, with water moving down its osmotic gradient to form GI secretions. Cl^- excretion is primarily renal, largely in the proximal tubule by passive reabsorption or cotransport. More regulated control of Cl^- excretion is performed in the intercalated cells of the distal nephron under the influence of plasma acid-base balance by exchange of HCO_3^- for Cl^-.

ACID-BASE DISTURBANCES AND FLUID THERAPY

Acid-base balance in general is discussed in Chapter 48; however, the two key areas in which intravascular fluid therapy may affect acid-base balance are iatrogenic acidosis caused by the administration of Cl^--rich fluids and administration of sodium bicarbonate to correct acidosis. In summary, the interpretation of acid-base balance can be viewed in three main ways: by the Henderson-Hasselbach equation, by anion gap, or by Stewart's strong ion model.

The Henderson-Hasselbach equation represents the HCO_3^- buffer system and has plasma HCO_3^- concentration as an independent determinant of plasma pH. The anion gap model is consistent with the Henderson-Hasselbach equation, because it places changes in plasma HCO_3^- at the core of plasma acid-base balance. It represents a simple method for differentiating causes of metabolic acidosis and is defined as the difference between the most abundant *measured* cation and anion concentrations in the plasma ($[Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-]$). The normal anion gap is 4 to 11 mEq/L, and this difference is represented by "unmeasured" anions (PO_4^{3-}, sulfate, and anionic proteins). In the presence of excess organic acids (e.g., lactic acid or ketoacid), the accumulation of unmeasured anions is accompanied by a reduction in HCO_3^- to buffer the excess H^+ ions, leading to an increase in the anion gap. In cases in which Cl^- is administered, even if HCO_3^- falls, the anion gap will remain normal.[35]

Stewart's model of acid-base balance has a different approach and proposes that plasma pH is dependent on the following three independent variables:

1. pCO_2 (the plasma CO_2 tension)
2. A_{tot}, the total plasma concentration of all nonvolatile buffers (albumin, globulins, and PO_4^{3-})
3. Strong ion difference (SID), the difference between the total charge of plasma-strong cations (Na^+, K^+, Mg^{2+}, and Ca^{2+}) and strong anions (Cl^-, lactate, sulfate, and others). In a more simplified approach, apparent SID is defined as $([Na^+] + [K^+]) - ([Cl^-] + [\text{lactate}])$. Normal plasma SID is approximately 42 mEq/L, and reductions in SID will lead to a fall in plasma pH.

The Stewart model has caused some controversy by representing HCO_3^- as a dependent variable,[36] but it has utility in explaining acid-base disturbances caused by fluid administration.[37]

Hyperchloremic Acidosis

Administration of fluid with Cl^- concentration higher than that of plasma will in sufficient quantities (e.g., 30 mL/kg/h of 0.9% saline) cause a metabolic acidosis due to the Cl^- content.[38] This hyperchloremic acidosis may be explained by the Henderson-Hasselbach model of acidosis, where saline infusion causes dilution of bicarbonate and a resultant base deficit, or by the Stewart model. Here, the increasing plasma Cl^- concentration reduces apparent SID and therefore reduces plasma pH; the SID of completely ionized saline is zero, therefore its infusion progressively dilutes the normal plasma SID. Similar changes are not seen with solutions containing non-Cl^- anions which are metabolized after infusion, such as lactated Ringer solution. Although in vitro as an electroneutral solution it also has an SID of zero, following administration, the lactate undergoes metabolism in patients with intact hepatic function, giving it an effective in vivo SID of approximately 29 mEq/L. This is slightly less than the plasma SID and is enough to counteract any alkalosis caused by dilution of A_{tot}.

Saline-induced hyperchloremic acidosis has a variety of potentially deleterious physiological effects. These include renal vasoconstriction, reduced GFR and reduced renin activity in animal models,[39–41] and reduced renal cortical perfusion in healthy volunteers.[42] Coagulopathy and gastrointestinal dysfunction have also been suggested.[43] However, it is not clear that acidosis purely attributable to iatrogenic hyperchloremia leads to clinically important morbidity. A meta-analysis of studies comparing saline with balanced perioperative fluid regimes confirmed the presence of hyperchloremia and acidosis postoperatively in the saline groups, but typically these biochemical abnormalities were cleared by the first or second postoperative day.[38] There were no overall differences in markers of kidney injury or need for renal replacement therapy, nor in other morbidities such as clinically important coagulopathy or gastrointestinal symptoms. However, the available trials were relatively small, and higher-risk surgical groups (those with pre-existing impairment of acid-base status, emergency and major surgery) were under-represented. Interestingly, in one trial of patients undergoing renal transplant, saline administration was associated with significant hyperkalemia, presumably caused by cellular potassium extrusion due to extracellular acidosis.[44] It is therefore possible that the acidosis observed due to saline administration has a greater clinical effect on a selected high-risk group. Recent large trials in the emergency department and intensive care settings have shown an increase in a composite outcome of death or adverse renal event when patients are given saline rather than balanced crystalloid.[45,46] The effect seemed to be greatest in medical patients with sepsis. The difference in composite outcomes was small (15.4% in the saline group, 14.3% in the balanced group), but this should be taken in the context of the large number of hospitalized patients that receive intravenous fluids. Although these trials did not relate specifically to the perioperative setting, an increasingly cautious approach to saline administration seems appropriate.

Bicarbonate Administration

The administration of IV $NaHCO_3$ to treat metabolic acidosis should be reserved for the emergency treatment of select conditions, including severe hyperkalemia and arrhythmias associated with tricyclic antidepressant overdose. In many other situations, clinical benefit is not apparent, a finding that highlights an important pathophysiologic concept. Acidosis in itself may not be physiologically deleterious; indeed, it is a normal event during strenuous exercise, in which it may aid O_2 offloading to tissues. Perhaps acidosis serves as a marker for the severity of underlying disease processes, such as hypoxia, ischemia, or mitochondrial dysfunction, which cause morbidity without adequate correction.[43] HCO_3^- administration also has the following negative effects[18]:

1. Carbon dioxide production. Most of the HCO_3^- administered is converted to CO_2, with two important consequences. First, excess CO_2 requires excretion by hyperventilation. Converted HCO_3^- of 100 mEq represents an excess of 2.24 L of CO_2 to be exhaled, which may present a significant physiologic challenge to critically ill patients with preexisting ventilatory impairment. Although this is disputed, the excess CO_2 may also diffuse into the intracellular space, aggravating intracellular acidosis.[18]

2. IV HCO_3^- brings a significant Na^+ content and therefore osmotic load. This may lead to hyperosmolar hypernatremia, ECF expansion, and volume overload.
3. If renal HCO_3^- distribution is impaired, there may be an "overshoot" toward metabolic alkalosis once the underlying disease process causing the initial acidosis is resolved.

In situations in which HCO_3^- administration is required, the total dose required to correct the base deficit can be calculated using the equation:[5]

$$\text{Dose (mEq)} = 0.3 \times \text{weight(kg)} \times \text{base deficit(mEq/L)}$$

Although half this dose is usually given, because of the problems outlined above, treatment should stop once the pH rises above 7.2.

Fluid Pharmacology

Given the diverse range of physiologic effects of administered fluids, and the potentially large volumes which can be administered perioperatively, they should be considered as drugs with specific indications, cautions, and side effects. Many of the fluids available currently were developed several decades ago and entered clinical practice without rigorous analysis of their clinical benefits, or knowledge of their effects at an organ or cellular level. Newer colloid solutions have been approved by regulatory authorities and entered widespread clinical usage based on relatively small trials of efficacy. In some cases, safety concerns such as the impact of colloid-related renal dysfunction have only been highlighted by much later adequately powered trials.[47] The composition of available fluids is shown in Table 47.6, although not all fluids are available in all countries.

CRYSTALLOIDS

Crystalloids are solutions of electrolytes in water. They may be classified by their tonicity after infusion or their overall composition. Crystalloids containing electrolytes found in plasma and a buffer such as lactate or acetate may be referred to as balanced solutions. Crystalloids are indicated for replacement of free water and electrolytes but also may be used for volume expansion. Conventional concepts of fluid compartments dictate that infused electrolytes will distribute freely throughout the ECF, water will follow down osmotic gradients, and the net result is a distribution of infused crystalloids throughout the entire ECF, with only 20% remaining in the intravascular compartment. This is challenged by large clinical trials and current knowledge of microvascular fluid handling (see the Vascular Endothelium section), which suggest that isotonic crystalloids may have a larger intravascular volume expanding effect than this, particularly in patients with low capillary hydrostatic pressures. The study of volume kinetics has quantified the redistribution of crystalloids from the central (intravascular) volume to the larger peripheral (total extracellular) volume. Perhaps up to 70% of a crystalloid infusion remains in the intravascular compartment at the end of a 20-minute continuous infusion, decreasing to 50% after 30 minutes.[4] Nevertheless, more fluid will ultimately be filtered out of the capillary with crystalloids than with colloids, owing to colloids' effects on oncotic pressure. Patients resuscitated with crystalloids have a more positive fluid balance for the same volume expansion effect.[51] Tissue edema may increase in compliant tissues such as the lung, gut, and soft tissues, particularly when crystalloid solutions are infused into normovolemic subjects. Large-volume crystalloid infusions also may be associated with a hypercoagulable state caused by dilution of circulating anticoagulant factors; the clinical significance of this is not currently known.[52]

Saline Solutions

0.9% Sodium Chloride. One of the most commonly administered crystalloids is 0.9% NaCl solution, yet it is not clear historically how it entered routine clinical practice. Although many of the crystalloids being examined for in vivo clinical usage during the 1800s had a composition much closer to that of plasma, Hamburger ascertained using in vitro red cell lysis experiments that 0.9% was the NaCl concentration that was isotonic with human plasma. Therefore, 0.9% saline was not initially developed with the aim of in vivo administration, yet has entered widespread clinical use despite having a Na^+ and Cl^- concentration far in excess of that of plasma.[53] Its osmolarity, calculated as the sum of the solutes present, is slightly higher than that of plasma, although the osmolality (measured by freezing point depression) is 285 mOsm/kg, very similar to that of plasma. This discrepancy reflects the nonideal behavior of solutions. Both ions remain in the ECF after infusion, and it can be said to be isotonic—that is, of a similar *effective osmolarity* to that of plasma with respect to the cell membrane.

A 2-L infusion of 0.9% NaCl leads to an increase in ECF volume, dilutional decrease in hematocrit and albumin, increase in Cl^- and K^+ concentrations, and decrease in plasma HCO_3^-.[42] The expansion of the ECF is more persistent than with balanced crystalloid solutions. Although both fluids induce diuresis, 0.9% NaCl has a later onset and the excess salt and water load may take multiple days for even a healthy subject to excrete.[12]

A 0.9% NaCL infusion leads to a hyperchloremic metabolic acidosis and reduced renal perfusion. Although important differences in clinical outcomes in the surgical populations are not clear,[54] in the wider critical care population an increased incidence of kidney injury and requirement for renal replacement therapy are seen when compared with the use of lower Cl^- solutions.[46,55] In healthy volunteers, large-volume (50 mL/kg) saline infusions lead to abdominal discomfort, nausea, and vomiting.

These side effects mean that the volume of saline administered perioperatively should be limited, unless there are compelling indications such as the following:

- Situations in which increased plasma Na^+ may be beneficial, such as in the presence of cerebral edema.
- Preexisting Na^+ or Cl^- total body depletion, such as gastric outlet obstruction (see later discussion). However, 0.9% NaCl is not suitable for the treatment of acute severe hyponatremia, because it has little effect on plasma Na^+ levels in this situation.

HES, Hydroxyethyl starch; *MWw,* weight-averaged mean molecular weight. Plasma-Lyte, PlasmaVolume, Baxter International, Deerfield, IL; Gelofusine, Gelaspan, Venofundin, Sterofundin, and Tetraspan, B Braun (Melsungen, Germany); Plasmion, Geloplasma, Voluven, and Volulyte, Fresenius-Kabi, Bad Homburg, Germany; Hextend, BioTime, Berkeley, Calif; Pentaspan from Bristol-Myers Squibb, Canada; Hemosol, Hosptal, Rugby, United Kingdom.; Isoplex Beacon, Kent, United Kingdom; Normosol, Hospira, Lake Forest, IL.

*Presented as mEq/L, except where stated.

†The NaCl content and osmolarity of albumin solutions varies dependent on formulation. Osmolarity values are calculated in vitro.

Hypertonic Saline. Solutions of 1.8%, 3%, and 7.5% NaCl are available. Their uses include:

Plasma volume expansion: The hypertonic nature of these solutions draws water out of the intracellular compartment and into the extracellular (including plasma) volume and may therefore achieve plasma volume expansion while minimizing the volume of fluid administered. Although it has not been studied extensively, use of hypertonic saline for trauma resuscitation, particularly in the prehospital phase, has not shown convincing benefit. In fact, one large trial showed no improvement in outcome and was stopped early.[56]

- Correction of hypoosmolar hyponatremia (see later discussion)
- Treatment of increased intracranial pressure: The increased plasma osmolality reduces cerebral edema and decreases intracranial pressure. Hypertonic saline may be superior to mannitol in this regard.[57] However, hypertonic saline used early in traumatic brain injury without knowledge of intracranial pressure has not been shown to be beneficial in clinical trials.[58]

At NaCl concentration greater than 7.5%, these solutions may cause endothelial damage; indeed, 11.7% NaCl may be used as a sclerosant agent and should therefore be administered into a central vein.

Balanced Crystalloid Solutions

Intravenous crystalloid solutions were initially used clinically for the management of cholera in 1832 by O'Shaughnessy and Latta. The early solutions were more closely matched to physiologic plasma composition than NaCl solutions and contained 134 mEq/L Na^+, 118 mEq/L Cl^-, and 16 mEq/L HCO_3^-.[53] However, clinical interest in more balanced solutions waned until Hartmann in 1932 used a lactated modification of Ringer solution for pediatric patients with acidosis associated with hypovolemia and liver and renal failure.[59] By this time, NaCl solutions were already in use for resuscitation from hemorrhage and trauma.[53]

Currently available balanced crystalloid solutions have lower overall osmolarity than 0.9% NaCl, with a lower Na^+ concentration and much lower Cl^- concentration (see Table 47.6). The reduction in anionic content is compensated for by the addition of stable organic anionic buffers such as lactate, gluconate, or acetate. The measured osmolality of balanced solutions (265 mOsm/kg) is slightly lower than that of plasma, and they are therefore mildly hypotonic. Fluid compartment distribution of balanced solutions is resembles that of other crystalloids. After administration, the buffer is metabolized to produce HCO_3^- in equimolar quantities by entry into the citric acid cycle. Lactate undergoes predominantly hepatic oxidation or gluconeogenesis to yield HCO_3^- at a maximum rate of approximately 200 mmol/h.[60] Acetate is normally present in trace quantities in the plasma (0.2 mM), because it is rapidly oxidized by liver, muscle, and heart to yield HCO_3^- at a maximum turnover of 300 mmol/h, beyond which zero-order kinetics intervene.[61] A small proportion may be converted to the acetoacetate. The metabolism of gluconate is less well characterized in terms of location and kinetics, but it is converted to glucose with subsequent entry into the citric acid cycle.[62] Although balanced crystalloids can be constituted with HCO_3^- as a main anion, this is limited by two factors. First, HCO_3^- reacts with water to form CO_2, which can diffuse out of most packaging materials. This has been addressed by some products, although availability is limited.[63,64] Second, the pH shift induced by the presence of HCO_3^- can lead to precipitation of Ca^{2+} (and Mg^{2+}) if present.

The excretion of the excess water and electrolyte load with balanced crystalloids is more rapid than with isotonic saline.[65] This is due to the transient decrease in plasma tonicity after infusion, which suppresses ADH secretion and allows diuresis in response to the increased intravascular circulating volume. Balanced crystalloids do not reduce plasma SID to the same degree as NaCl solutions and therefore do not cause an acidosis; HCO_3^- concentration is maintained or slightly elevated.

Some potential negative effects have been identified with balanced crystalloid solutions. Lactated Ringer solutions contain racemic (D- and L-) lactate, although D-lactate is only found in trace quantities in vivo. Concerns that large doses of D-lactate may be associated with encephalopathy and cardiac toxicity in patients with renal failure[66,67] have not been confirmed in human studies at plasma levels achievable with racemic lactated Ringer solution. The metabolism of D-lactate appears to be nearly as rapid as that of L-lactate.[68] The reliance on hepatic metabolism of most of the infused lactate means that lactated solutions should be avoided in severe liver failure. Concerns over the negative effects of excess exogenous acetate have been raised in patients receiving dialysis with an acetate-based dialysate. The proinflammatory, myocardial depressant, vasodilatory, and hypoxemia-promoting effects of high acetate levels manifest as nausea, vomiting, headaches, and cardiovascular instability and have led to the removal of acetate from contemporary dialysis fluids.[61,69–73] Acetate turnover is limited in patients with end-stage kidney disease and by the presence of other substrates for oxidation—for example, during lactic acidosis or proteolysis. It is therefore possible that critically ill patients or those with advanced kidney disease may exhibit biochemical acetate intolerance, although this possibility has not been explored in patients receiving acetate-based balanced crystalloids. Unlike acetate, much less is known about the effects of gluconate-containing fluids.[74] Indeed, this area requires investigation at a cellular, organ, and whole organism level, particularly because data in animal studies suggest poorer outcome and late increases in lactate in a hemorrhage model when acetate/gluconate-containing crystalloids are compared to lactated Ringer solution or isotonic saline for resuscitation.[75]

Dextrose Solutions

Dextrose solutions have the following two main indications in the perioperative setting:

1. As a source of free water: An infusion of 5% dextrose effectively represents administration of free water. The in vitro osmolality resembles that of plasma so the infusion does not lead to hemolysis, but soon after administration, the dextrose is taken up into cells in the presence of insulin, leaving free water. These solutions are therefore hypotonic with respect to the cell membrane and

in excess can dilute plasma electrolytes and osmolality. They should therefore be used with care in the postoperative period, during which the relative syndrome of inappropriate secretion of antidiuretic hormone (SIADH) leads to water retention, increasing the risk for hyponatremia (see later discussion). Nevertheless, in carefully controlled volumes and with regular monitoring of serum electrolytes, they are a useful source of free water for maintenance requirements postoperatively, particularly if combined with a low concentration of NaCl. Dextrose solutions are less suitable for intravascular plasma volume expansion, because water can move between all fluid compartments, and a very small volume remains in the intravascular space.

2. Source of metabolic substrate: Although the caloric content of 5% dextrose is inadequate to maintain nutritional requirements, higher concentrations are adequate as a metabolic substrate, such as 4000 kCal/L for 50% glucose. Glucose solutions also may be coadministered with IV insulin to diabetic patients to reduce the risk for hypoglycemia, such as 10% dextrose at 75 mL/h.

COLLOIDS

Colloid is defined as large molecules or ultramicroscopic particles of a homogeneous noncrystalline substance dispersed in a second substance, typically isotonic saline, or a balanced crystalloid. These particles cannot be separated out by filtration or centrifugation. Although not all solutions are available in all countries, those in production include semisynthetic colloids and human plasma derivatives. Semisynthetic colloids have a range of molecular sizes (polydispersed) in contrast to human albumin solution, which contains more than 95% albumin molecules of a uniform size (monodispersed). Colloid molecules above 70 kDa are too large to pass through the endothelial glycocalyx and are excluded from the subglycocalyx layer, so their initial volume of distribution is the plasma (rather than the entire intravascular) volume (see discussion of vascular endothelium). In contrast to pure electrolyte solutions, colloids have a higher COP and minimize transcapillary filtration, particularly at low capillary hydrostatic pressures. This maximizes their potential intravascular plasma volume expansion effect. However, at normal or supranormal capillary pressures, hydrostatic pressure will be increased and transcapillary filtration will occur.[3] In addition, colloid molecules may be lost from circulation in several ways—by filtration across capillaries whose barrier function is impaired by glycocalyx shedding or endothelial cell pore formation in inflammation or other stressors, by renal filtration of smaller colloid molecules, or by removal from the circulation by metabolism. Therefore, colloids have variable effective plasma half-lives, as outlined later. Colloids alter blood rheology, improving blood flow by hemodilution which leads to reductions in plasma viscosity and red cell aggregation.[52] In contrast to their beneficial effects, the introduction of a large dose of semisynthetic molecules (typically 40-60 g/L) to a complex physiologic system may bring a variety of undesired effects on the immune, coagulation, and renal systems. To limit these toxicities, maximum dosages are recommended for most colloids, but adverse effects may still occur with lower doses. As the potential clinical relevance of toxicity is highlighted by large clinical trials, the use of colloids, at least in critical care, deserves increasing caution.[76] Whether these trials in critical care can be applied to the entire perioperative period has not been established. The evolving evidence base on the differential effects of isotonic saline or balanced crystalloid is also likely to focus more attention on the carrier solute used in colloids.

Semisynthetic Colloids

Gelatins. Gelatins are derived from the hydrolysis of bovine collagen, with subsequent modification by succinylation (Gelofusine, B Braun, Bethlehem, Pa; Geloplasma®, Fresenius, Waltham, MA) or urea-linkage to form polygeline (Haemaccel, Piramal, Orchard Park, NY). These forms have a similar molecular weight (MW), but the succinylated version undergoes conformational change as a result of increased negative charges, such that it is a larger molecule. The wide range of MWs means that much of an infused gelatin bolus will rapidly leave the circulation, predominantly by renal filtration. Despite this, a recent study suggests that 60 minutes after the end of infusion, 50% of the infused fluid volume remains in the intravascular space, similar to larger MW colloids.[77] Excretion is primarily by the renal route. In terms of negative effects, the gelatins have the least impact on clinically relevant hemostasis of all the semisynthetic colloids despite reductions in von Willebrand factor (vWF), factor VIIIc, and ex vivo clot strength,[78] but the highest estimated incidence of severe anaphylactic and anaphylactoid reactions (<0.35%).[52] The high Ca^{2+} content of Haemaccel is a contraindication to coadministration of citrated blood products in the same infusion set. No known cases of variant Creutzfeldt-Jakob disease transmission have occurred involving pharmaceutical gelatin preparations. Gelatins are commonly used in perioperative practice in Europe but are not approved by the U.S. Food and Drug Administration.

Hydroxyethyl Starches. Hydroxyethyl starches (HESs) are modified natural polymers of amylopectin derived from maize or potato. Substitution of hydroxyethyl radicals onto glucose units prevents rapid in vivo hydrolysis by amylase, and the degree of substitution both in terms of hydroxyethyl substitutions per glucose unit (maximum three) and total number of glucose units with substitutions is a determinant of HES elimination kinetics. The degree of substitution (DS) is expressed as the number of substituted glucose molecules present divided by the total number of glucose molecules present. An alternative measure of substitution is the molar substitution (MS) ratio, calculated as the total number of hydroxyethyl groups present divided by the quantity of glucose molecules. MS is used to define starches as hetastarches (MS 0.7), hexastarches (MS 0.6), pentastarches (MS 0.5), or tetrastarches (MS 0.4). The pattern of substitution may vary because hydroxyethylation can occur at carbon positions 2, 3, or 6 of the glucose unit. The substitution type is defined by the C2/C6 hydroxyethylation ratio, and a higher ratio leads to slower starch metabolism. Starches are also classified by in vitro MW into high (450-480 kDa), medium (200 kDa), and low (70 kDa). However, HES solutions are very polydispersed and the MW quoted is an average. The size of starch molecule is responsible for both the therapeutic volume effects and adverse side effects. After administration, smaller HES molecules (<50-60 kDa) are rapidly excreted and larger molecules are hydrolyzed to form a greater number of smaller molecules at a rate depending on the degree of substitution and C2/C6 hydroxyethylation ratio. The in vivo MW is therefore smaller and has a narrower distribution.[79] Ongoing renal excretion accounts for the elimination of smaller HES molecules, with medium-sized molecules being excreted in the bile and feces. A proportion of larger molecules, particularly those resistant to hydrolysis, is taken up by the mononuclear phagocyte (reticuloendothelial) system, where they may persist for several weeks or more.[80] The prolonged metabolism of HES means that their plasma volume effects typically last longer than those of gelatins or crystalloids. Larger MW starches can increase intravascular volume by approximately 70% to 80% of the infused dose even at 90 minutes.[81] Smaller MW starches with a low MS may have even larger volume effects as a result of the rapid initial metabolism with the formation of a large number of oncotically active molecules,[82] but studies in healthy human volunteers suggest only a similar volume effect to that of gelatins.[77]

For all fluids in this category, starch-related side effects have been associated with adverse outcomes in critical illness. Problems such as coagulopathy, accumulation, and renal dysfunction initially appeared to be related to larger MW starches, but now smaller tetrastarches are a concern as well. Despite this, study populations with critical illness, particularly sepsis, cannot be compared directly with elective perioperative patients. These trials should be interpreted with caution when considering the relevance of HES to surgical patients. Nevertheless, the official recommendations against the use of HES are clearly negative.

Coagulation. As with other synthetic colloids, HES products affect coagulation through dilutional effects in the circulation and MW-dependent reductions in vWF, factor VIII, and clot strength. The effect is most likely to occur with larger MW or slowly degraded medium MW (200 kDa/MS 0.62 or 200 kDa/MS 0.5/C2:C6 13) HES preparations and larger amounts of perioperative blood loss. This clinical effect is less marked with more rapidly degraded medium and small MW starches.[52] In patients with sepsis, even lower MW HES is associated with an increased risk of bleeding and blood transfusion, but it is unclear whether this also occurs in the perioperative setting.[83,84]

Accumulation. The accumulation of HES molecules in the mononuclear phagocyte system and skin, liver, muscle, and gut is a dose-dependent effect that gradually decreases over time. However, the accumulation may persist for several years, and larger amounts of tissue deposition are associated with pruritus.[80]

Anaphylactoid Reactions. The estimated incidence of severe anaphylactoid or anaphylactic reactions with HES products is less than with other colloids (<0.06%).[52]

Renal Dysfunction. HES products with medium-to-high MW are associated with oliguria, increased creatinine, and acute kidney injury in critically ill patients with preexisting renal impairment.[6,85] Although newer solutions with low MW (130 kDa/MS 0.4) were initially thought to be safer in this respect, recent large-scale trials have shown a similar effect on the need for renal replacement therapy in severe sepsis, particularly when compared with balanced crystalloids.[83,84] A recent large trial in a mixed critical care population comparing HES with isotonic saline also reported an increase in renal replacement therapy with the starch solution. This study is more difficult to interpret, given the potential renal effects of saline, and, as with previous studies, the possibility that patients were given study fluids after partial resuscitation had already been achieved.[51] Currently, no similar data are available from large-scale studies on the intraoperative use of HES solutions, and a recent meta-analysis examining perioperative use of 6% HES concluded that although no increase in mortality or kidney injury was seen, the available evidence lacked statistical power to definitively answer this question.[86] Meanwhile, the use of starch-based colloids has been restricted or even completely suspended by regulatory authorities in both the United States and Europe.

Dextrans. Dextrans are highly branched polysaccharide molecules produced by the bacterium *Leuconostoc mesenteroides* after conversion of sucrose in the growth medium by bacterial dextran sucrase. The large-MW dextrans produced undergo acid hydrolysis to yield smaller MW molecules, which are then separated by fractionation to produce a solution with a restricted range of MWs. Available dextrans have an average MW of 40 kDa or 70 kDa. As with other colloids, the polydisperse nature of dextran solutions means that a proportion of smaller MW molecules are present that are rapidly filtered at the glomerulus; 70% of a dextran dose is renally excreted within 24 hours. Higher MW molecules are excreted into the GI tract or taken up into the mononuclear phagocyte system, where they are degraded by endogenous dextranases.[52] Dextrans have a plasma volume effect similar to that of starches, with a duration of 6 to 12 hours. In addition to their use in volume expansion, dextran 40 may be used in microvascular surgery, where its dilutional effects on blood viscosity and anticoagulant effects (see later discussion) favor flow in the microcirculation. Overall, the use of dextrans is limited by their range of toxicities.

Antithrombotic effect: This is particularly marked in lower MW dextrans and is mediated through a range of mechanisms, including red cell coating and inhibition of aggregation, factor VIIIc and vWF reductions, and impaired activity of factor VIII. Platelet aggregation is also inhibited. The result is clinically impaired hemostasis and increased perioperative blood loss.[78]

- Blood cross-matching: Dextrans coat the erythrocyte cell membrane and may interfere with blood type cross-matching.
- Anaphylactoid reactions: Dextrans have an intermediate risk for serious anaphylactic and anaphylactoid reactions (<0.28%). Preemptive treatment with dextran 1, a hapten inhibitor, may reduce this incidence to less than 0.0015%.[52]
- Renal dysfunction: Renal dysfunction resulting from osmotic nephrosis is recognized after low-MW dextran infusion,[87] although the true incidence of this phenomenon in perioperative patients is difficult to estimate

because of the limited use of dextrans in contemporary practice.

Human Plasma Derivatives

The human plasma derivatives include human albumin solutions, plasma protein fractions, fresh frozen plasma, and immunoglobulin solution. Preparation techniques result in relatively purified solutions with the elimination of infective agents, although the theoretic risk for transmission of variant Creutzfeldt-Jakob disease and associated bovine spongiform encephalopathy remains. One U.K. case of presumed prion transmission has been described in association with factor VIII transfusion, although without clinical manifestation.[88] The ongoing transmission risk has been mitigated by sourcing many plasma derivatives from non-U.K. sources.

Solutions such as 5% albumin have a near-physiologic COP of 20 mm Hg and are used for volume expansion. Despite the association of hypoalbuminemia with worse outcomes from critical illness, the administration of exogenous albumin does not improve outcome in these situations. Early concerns that resuscitation with albumin may actually increase mortality in critical illness were not confirmed by a large controlled trial that found no difference in outcomes whether albumin or isotonic saline was used for resuscitation.[5] In this heterogeneous population, the albumin group required less fluid to attain similar endpoints (ratio 1:1.4), although in the subgroup of patients with trauma, and particularly brain injury, albumin may be associated with an increased incidence of mortality.[5,89] Conversely, in a subgroup analysis of patients with sepsis, albumin administration trended toward a decreased frequency of mortality that was supported by a subsequent meta-analysis.[90]

Clinical Fluid and Electrolyte Management

PATHOPHYSIOLOGIC FLUID ALTERATIONS IN THE PERIOPERATIVE PHASE

Before recommending practical approaches to administering fluid in the perioperative phase, it is important to consider the pathophysiologic processes, which affect not just the body's requirement for exogenous fluid and electrolytes but also the manner by which fluids are distributed by the body. The patient may enter the perioperative phase with abnormalities of intravascular fluid volume and distribution. Subsequent trauma (including surgery) induces a range of evolutionarily conserved neurohumoral and inflammatory changes, termed the stress response, which may have a significant impact on fluid and electrolyte responses and distribution. When the stress response is of an appropriate magnitude and duration, it can be a beneficial process for recovery from trauma; however, it could become pathologic if it is either exaggerated or prolonged or presents a physiologic burden to patients with limited baseline physiologic reserves.

Preoperative

Patients may enter the perioperative phase with established derangements of fluid and electrolyte balance. Hepatic, renal, and cardiac dysfunction are all associated with disordered Na^+ distribution (see later discussion), which has profound secondary effects on ECF volume. Patients with end-stage renal disease depend on dialysis for fluid removal, and the timing of dialysis relative to surgery is critical. Chronic treatment with diuretics may also lead to electrolyte depletion. Depending on the treatment, hypertensive patients may have a volume-contracted circulation, making them prone to intraoperative hypovolemia.

The effects of preoperative fasting also should be considered, although its influence on fluid balance has perhaps been overstated. Modern perioperative practice mandates cessation of oral fluids only 2 hours before elective surgery, and overnight fasting usually does not result in changes to normal blood volume when measured using robust experimental techniques.[91] Conversely, bowel preparation can cause a weight loss of 1.5 to 1.7 kg[92,93] with a high water and K^+ content. The potentially deleterious effects of this should be limited by restricting bowel preparations when possible and compensating for fluid loss with simultaneous IV infusion of 1 to 2 L of crystalloid with K^+ supplementation, which can improve hemodynamics and lower serum creatinine.[93]

More severe disturbances of fluid and electrolyte balance can occur in patients presenting with acute disease requiring surgical intervention:

- Direct intravascular depletion from bleeding.
- Loss of fluid from the GI tract. This results in ECF depletion and loss of electrolytes, depending on the GI tract location. Excess gastric loss because of obstruction, vomiting, or excess nasogastric suction results in loss of Na^+, K^+, Cl^-, and acid. Loss of small bowel secretions results in high losses of Na^+, Cl^-, and HCO_3^- with lesser K^+ losses. Large bowel losses, such as in diarrhea, deplete large quantities of K^+ with lesser losses of Na^+ and HCO_3^-. Pathologic fluid sequestration within the bowel lumen may have similar effects without external signs of fluid loss.
- Inflammation-related redistribution from the intravascular to the extracellular compartment (see later discussion).
- Fluid sequestration in the physiologic third space, with edema, pleural effusions, and ascites.

Intraoperative

Many factors influence intraoperative fluid balance, such as:

- Altered distribution of intravascular volume. Anesthetic agents lead to vasodilation, which can affect both the venous and arterial systems and may reduce cardiac preload and afterload. This reduction may be exacerbated by sympathetic blockade caused by central neuraxial blockade, and cardiac output may also be decreased by the negative inotropic effect of anesthetic drugs. The distribution of blood within the vascular system is also influenced by the differential blunting of autoregulatory responses within organ beds caused by anesthesia. Microcirculatory dysfunction related to the effects of anesthesia and the inflammatory response to surgery may result in impaired functional matching of local O_2 delivery with tissue O_2 requirements, which may not be responsive to intravascular fluid therapy.

- Direct loss of intravascular volume from hemorrhage. The clinical manifestation of surgical blood loss may vary greatly depending on the volume and time course of the blood loss.
- Insensible losses. The opening of anatomic compartments leads to evaporative fluid loss from mucosal surfaces, although estimating the extent of this loss may be difficult. Humidity chamber studies indicate that the loss may be as little as 1 mL/kg/h even during a major laparotomy with extensive bowel exposure.[94]
- Inflammation-related redistribution. Major surgery induces an inflammatory response that redistributes fluid from the intravascular to the extracellular compartment. This typically manifests in the postoperative phase (see later discussion), although it may become clinically apparent intraoperatively during surgery of sufficient magnitude and duration.
- Renal output. The suppression of renal urine production is related to perioperative ADH secretion and may also be influenced by the effects of positive-pressure ventilation. Increased intrathoracic pressure reduces venous return and cardiac output, which combine with a variety of neurohumoral responses such as sympathetic activation and suppression of ANP release to decrease GFR and urine output.[95] As a result, intraoperative urine output may be low regardless of the volume of IV fluid administered.[96]

The early phase of the stress response is triggered during major surgery. Absolute or relative (redistributive) hypovolemia during the intraoperative phase invokes a range of conservative responses—described in the section on Acute Disturbances in Circulating Volume—that are aimed at redistributing blood away from the periphery and toward vital organs and maintaining circulating volume by retaining salt and water. The tissue trauma of surgery also triggers a well-described inflammatory and immune response, and together these changes may persist into the postoperative phase. The inflammatory response elicited by tissue trauma may be aggravated by periods of hypotension and tissue hypoperfusion.

Postoperative

As a result of the preoperative and intraoperative factors outlined previously, patients may start the postoperative phase with significant derangements of intravascular volume and fluid compartment distribution. The stress response triggered by surgery may also have an ongoing influence on postoperative fluid balance.

Inflammation and Immune Response. Tissue injury leads to local vasodilation, increased endothelial permeability, and influx of leukocytes to the damaged area, with consequent production of proinflammatory cytokines for up to 72 hours, particularly interleukin-1 (IL-1), TNF-α, and IL-6. Cardiopulmonary bypass, extensive tissue trauma, or surgery in areas with subclinical preoperative inflammation, such as tumor or infection, may lead to a postoperative systemic inflammatory response syndrome (SIRS). An alternative trigger for SIRS is GI hypoperfusion. The physiologic response to hypovolemia is preservation of cardiac and brain perfusion at the expense of kidney, gut, and peripheral perfusion. The intestinal villi have a countercurrent blood supply that shunts blood away from the mucosa in this situation, leading to mucosal necrosis and further impairment of gut barrier function by luminal digestive enzymes and bacteria. This allows gut bacterial endotoxin to translocate into the systemic circulation, acting as a potent trigger for systemic inflammation.[97,98] The reactive O_2 species released on reperfusion of compromised bowel further aggravate the inflammatory cascade.

Systemic inflammation impairs endothelial barrier function through changes in endothelial cell phenotype, increases in endothelial large pores, and degradation of the endothelial glycocalyx.[2] Hypervolemia caused by excessive fluid infusion leads to the release of cardiac natriuretic peptides, which may further degrade the endothelial glycocalyx.[9,99] In severe cases, inflammation-related endothelial dysfunction leads to a capillary leak syndrome, with loss of water, electrolytes, and proteins into the interstitial space causing edema in the lungs, bowel, and connective tissue. Reduced plasma oncotic pressure facilitates ongoing capillary fluid filtration into the extravascular space and consequent hypovolemia.

Catabolic Metabolism. The response to tissue injury requires an increase in energy substrate delivery, particularly to leukocytes involved in the acute inflammatory and immune reaction. This metabolic shift is mediated by catecholamine and cortisol release and involves muscle protein catabolism, with associated hepatic gluconeogenesis and acute phase protein production, and increased substrate delivery to damaged tissues. An increase in basal metabolic rate and adequate circulating volume are required to meet the needs of increased fuel mobilization, processing, and delivery.

Regulation of Salt and Water Balance. As described in the section on physiologic control of overall fluid balance, ADH release is induced during surgery, leading to postoperative retention of water. This may be a direct result of the acute stress response, and IL-6 has been proposed as a key mediator.[100] In addition, periods of hypovolemia and hypotension further stimulate ADH release and activate the RAA system with further water and salt retention and amplified ADH production. This may lead to a temporary period of oliguria despite a restored circulating volume and the risk for postoperative fluid overload and sodium fluctuations. Na^+ retention postoperatively is more pronounced in the hypercatabolic state after major surgery, as excess nitrogen competes with Na^+ for renal excretion.

In addition to these processes, fluid may be lost from the circulating volume as a result of reaccumulation into third spaces drained intraoperatively (ascites or pleural effusions), sequestration into the bowel lumen or removal through vomiting, nasogastric drainage, or stoma losses. Intravascular fluid *distribution* is also a dynamic situation postoperatively because of changes in vascular tone caused by rewarming, evolving epidural sympathetic blockade, or systemic inflammation.

ASSESSMENT AND TREATMENT OF PERIOPERATIVE FLUID AND ELECTROLYTE IMBALANCE

Intravascular Volume

As a key variable influencing cardiac output (preload), and therefore tissue O_2 delivery, intravascular volume is at the core of adequate tissue perfusion. Although the assessment of intravascular volume is an important part of perioperative fluid therapy, it may be challenging. Clinical history suggesting abnormal volume status should be sought (see earlier discussion) and accompanied by frequent clinical examinations, although many of the conventional markers of volume status are not reliable when taken in isolation. Obvious hypovolemia may manifest with tachycardia, reduced pulse pressure, hypotension, and increased capillary refill time, but the abnormalities of these individual physiologic variables may have numerous causes in the perioperative phase. Conversely, loss of up to 25% of blood volume may not be accompanied by significant hemodynamic alterations in healthy patients.[101] Urine output, frequently taken as a measure of adequate end-organ perfusion, may also be reduced postoperatively, even in the presence of normal circulating volume, as a result of ADH and RAA activation. More invasive measures of intravascular volume also have limitations. CVP is used as a marker of central venous volume, but it is also influenced by venous compliance. CVP may be normal or high in venoconstricted states even when the absolute vascular volume is reduced. Furthermore, the relationship between right-heart and left-heart filling pressures is not reliable in the presence of cardiopulmonary pathologic processes. Trends in CVP values over time may be a more useful marker, because static CVP readings are poorly predictive of subsequent responses to intravascular fluid challenges.[102] Stroke volume (SV) and cardiac output may be measured using a variety of techniques, and targeting these variables has been widely investigated in perioperative fluid management, as described later. Alternatively, the adequacy of tissue perfusion may be assessed at a whole organism level using blood lactate concentrations, which may also be elevated during reperfusion of ischemic tissue or in advanced liver failure, or mixed venous O_2 saturation, which identifies a mismatch between global O_2 delivery (DO_2) and O_2 usage (VO_2). Techniques used to assess the perfusion of individual organs have the potential to detect clinically occult hypovolemia affecting those tissue beds or surgical sites most at risk for hypoperfusion, such as the gut. These include near-infrared spectroscopy,[103] microdialysis,[104] and GI CO_2 and pH measurement. The latter technique is gastric tonometry and is based on the association between inadequate gut perfusion and mucosal hypercarbia and acidosis.[105] It may detect hypovolemia of a magnitude not detectable by changes in systemic blood lactate, SV, or other cardiovascular parameters[101] that is nevertheless associated with increased postoperative morbidity.[106] Despite some encouraging findings in early research studies, none of these monitors is currently in routine use for guiding perioperative hemodynamic therapy.

Both excessive and inadequate intravascular volume can have adverse physiologic effects and achieving the fine balance between the two is a key goal of perioperative fluid administration. This concept of the "sweet spot" of fluid volume is backed up by large clinical datasets showing associations between both under- and over-resuscitation and postoperative morbidity.[107] Modest hypovolemia, through its effects on gut perfusion and stimulation of protective neurohumoral reflexes, may exacerbate the inflammatory and antidiuretic aspects of the surgical stress response. More severe hypovolemia reduces preload, cardiac output, and therefore DO_2. The result may be inadequate DO_2 to meet metabolic demands, with an increase in O_2 extraction ratio (reflected in reduced mixed venous O_2 saturation), progressing to inefficient anaerobic ATP production if mitochondrial oxidative phosphorylation cannot be sustained. This situation may be aggravated by insufficient compensatory increases in cardiac output, impaired microvascular blood flow, or failure of cellular O_2 usage. Lactate is a by-product of anaerobic metabolism and its accumulation leads to a metabolic acidosis. ATP production may be inadequate to support normal cell functions in tissues with poor perfusion, leading to cell death and organ dysfunction in the most extreme circumstances. Inadequate global O_2 delivery has been associated with a range of postoperative morbidities and increased mortality and has been the target of numerous clinical trials. At an individual organ level, specific areas that have been manipulated surgically, such as tissue flaps and bowel anastomoses, may be susceptible to poor healing and failure when local perfusion is insufficient.

Hypervolemia also has adverse effects and is often an iatrogenic problem in the perioperative setting. Crystalloids or colloids administered when capillary hydrostatic pressures are normal or increased lead to increased capillary filtration of fluid into the interstitial space. If this exceeds the capacity of the lymphatics to return the excess fluid to the circulation, edema will develop in compliant tissues such as the lungs, muscle, and bowel. The effect is more pronounced if inflammation or deterioration of the glycocalyx reduces the endothelial barrier function opposing the passage of large molecules into the interstitium. The correction of salt and water overload is a slow process because of inefficient renal handling of excess Na^+ loads, and the effects of postoperative ADH secretion. Clinically significant edema contributes to postoperative GI dysfunction, although this is not well defined by small clinical trials.[108,109] Further potential effects of excessive intravascular fluid include reduced tissue oxygenation with impaired healing, pulmonary congestion predisposing to pulmonary infection, and increased myocardial work resulting from ventricular filling beyond the optimum portion of the Starling curve.[110] Side effects may occur that are attributable to the amount of fluid given, such as hypercoagulability or hypocoagulability, hyperchloremic acidosis, or renal dysfunction. A positive fluid balance and weight gain in the early perioperative period increases postoperative morbidity.[111,112]

Electrolyte Imbalance

Sodium Disorders

HYPONATREMIA. Hyponatremia may be present preoperatively, develop as a consequence of perioperative events, or both. It is classified as mild (130-134 mEq/L), moderate (120-130 mEq/L), or severe (<120 mEq/L). Moderate-to-severe hyponatremia, particularly of acute onset, is associated with significant perioperative morbidity.

CAUSES. Assessment of serum osmolality, TBW status, and urinary Na^+ concentration is vital for the accurate diagnosis of the underlying cause of hyponatremia.[113,114] A diagnostic algorithm with common causes is shown in Fig. 47.3. Na^+ is normally the key determinant of serum osmolality, and hyponatremia is usually observed in conjunction with reduced osmolality. In some situations, however, osmolality is normal or raised by the presence of solutes that induce cellular dehydration and translocation of water from cells to

Fig. 47.3 Causes and diagnostic algorithm for hyponatremia. The diagnostic criteria for the syndrome of inappropriate antidiuretic hormone secretion *(SIADH)* include exclusion of adrenal, thyroid, and renal disease or diuretic usage, serum hypoosmolality (<270 mOsmol/kg), clinical euvolemia, increased urinary [Na^+] despite normal water and salt intake and inappropriate urinary concentration (>100 mOsmol/kg). A characteristic response to water restriction occurs, with a 2- to 3-kg fall in weight accompanied by a reduction in salt wasting over 2 to 3 days. *RTA,* Renal tubular acidosis; *TBW,* total body water; *TURP,* transurethral resection of the prostate; *U[Na^+],* urinary sodium concentration in mEq/L. the ECF. These include glucose in the absence of adequate insulin, mannitol, maltose, and glycine. Alternatively, hyponatremia may be artifactual (pseudohyponatremia), caused by the presence of high lipid concentrations. In hypoosmolar hyponatremia, imbalanced gains or losses of TBW and Na^+ occur such that serum Na^+ concentration is reduced.

Preoperative hyponatremia. Hyponatremia may be an incidental finding during preoperative assessment, with the underlying pathologic mechanisms identified in Fig. 47.3. Even mild preoperative hyponatremia is associated with increased 30-day mortality, major cardiac events, wound infection, and pneumonia.[115] Whether hyponatremia is a direct causal mechanism in postoperative adverse events or a marker of underlying overt or subclinical pathologic processes, such as cardiac failure, is not clear, although excess risk is seen even in American Society of Anesthesiologists (ASA) class 1 and 2 patients undergoing elective surgery. Interestingly, correcting preoperative hyponatremia does not clearly improve outcomes. The finding of preoperative hyponatremia should prompt a search for, and optimization of, potential underlying diseases. In moderate-to-severe hyponatremia, nonurgent surgery should probably be postponed to allow for gradual correction of hyponatremia (see later discussion).

Postoperative hyponatremia. As previously discussed, the surgical stress response, aggravated by periods of hypotension and pain-related or physiologic stress-related sympathetic activity, can lead to a state of Na^+ and water retention similar to SIADH. Avid water retention puts postoperative patients at risk for hyponatremia, particularly when administration of free water from IV dextrose-containing or other hypotonic solutions is ongoing. The incidence of postoperative hyponatremia is 1% to 5%, with children and premenopausal females at particularly high risk for neurologic

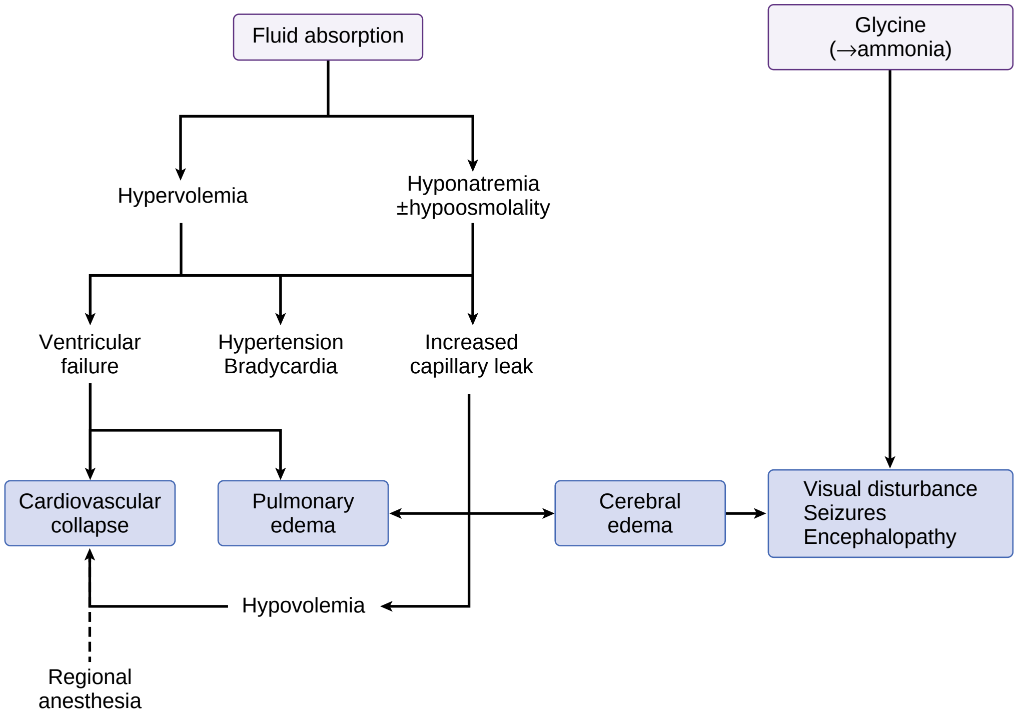

Fig. 47.4 The transurethral resection of the prostate (TURP) syndrome. Early hypervolemia-related hypertension may be followed by profound hypotension as a result of increased capillary filtration with hypovolemia, depressed cardiac function, and sympathetic blockade. Glycine itself may lead to seizures through allosteric activation of the *N*-methyl-D-aspartate receptor and is thought to cause the visual disturbance of the TURP syndrome. The hepatic deamination of glycine yields ammonia, which can further contribute to encephalopathy. (Modified from Gravenstein D. Transurethral resection of the prostate [TURP] syndrome: a review of the pathophysiology and management. *Anesth Analg.* 1997;84:438.)

symptoms. In these groups, symptoms and neurologic sequelae may occur at Na^+ levels as high as 128 mEq/L. Elderly women typically do not become symptomatic until 120 mEq/L, unless the decrease is particularly rapid. The potential impact of postoperative hyponatremia is considerable; 8% of hyponatremic patients may develop encephalopathy, of whom 52% suffer permanent neurologic sequelae or death.[116] Failure to recognize hyponatremia as a cause of postoperative symptoms (see later discussion) or inadequate treatment based on fears of causing osmotic demyelination may contribute to these poor outcomes.[117] Prevention of postoperative hyponatremia should be a key goal of postoperative fluid therapy, based on limiting free water administration to pure maintenance requirements (1-1.2 mL/kg/h), replacing losses of Na^+-containing fluids (e.g., GI) with an appropriate isotonic salt solution, stopping IV therapy as soon as the oral route can be used, and daily (or more frequent in high-risk groups) monitoring of serum electrolytes.

TRANSURETHRAL RESECTION OF THE PROSTATE SYNDROME. The transurethral resection of the prostate (TURP) syndrome describes symptomatic hyponatremia, excessive intravascular volume, and edema resulting from IV absorption of hypotonic nonconductive (electrolyte-free) irrigation fluid during TURP or, rarely, transurethral resection of the bladder[118] or during ureteroscopic or hysteroscopic procedures. The syndrome may complicate 10% to 15% of TURP procedures, with onset between 15 minutes and 24 hours after the onset of resection.[119] Risk factors include increased intravesical pressure, prolonged resection, hypotonic irrigants, and open prostatic sinuses. The clinical features (Fig. 47.4) are related to intravascular volume changes, hyponatremia, and absorption of irrigant solutes; the use of distilled water as an irrigant has largely been replaced by solutions of glycine, sorbitol, or mannitol because of the incidence of massive hemolysis. Hyponatremia resulting from free water absorption may lead to hypoosmolality, although the presence of glycine or other osmotically active solutes may maintain osmolality in the normal range. The following measures may help prevent the TURP syndrome:

- The use of conducting (isotonic saline) irrigant with bipolar diathermy.[120]
- Monitoring fluid absorption by comparing the amount instilled with the amount removed. Surgery should be halted if 750 mL (for females) or 1000 mL (for males) has been absorbed and the patient should be assessed for Na^+ levels and neurologic status (if awake). Surgery should be terminated if 1000 to 1500 mL (for females) or more than 2000 mL (for males) has been absorbed. If saline irrigant is used, surgery should be terminated after 2500 mL has been absorbed. Although the risk for hypoosmolar hyponatremia is removed, the risk for excessive intravascular volume remains.[121,122]
- Limiting the duration of irrigation: irrigation should continue only for longer than 1 hour after careful assessment of the patient for possible TURP syndrome.
- Limiting intravesical pressure to less than 15 to 25 mm Hg or 70 mm Hg for endometrial procedures.
- Monitoring the patient's neurologic status by using regional anesthetic techniques. Symptoms in the awake patient include nausea and vomiting, visual disturbance, reduced level of consciousness, agitation, confusion, and seizures.

Treatment of the TURP syndrome should take into account the patient's intravascular volume status, Na^+ level, and osmolality, but typically involves cessation of irrigation solutions and water restriction. A loop diuretic should be given to promote free water excretion if intravascular volume overload is present. In severe hypoosmolar hyponatremia with neurologic symptoms, hypertonic saline may be used. When osmolality is normal or marginally decreased, hemodialysis is preferred.[123] Mg^{2+} can be given for seizures, because its negative control of NMDA receptors counteracts dilutional hypomagnesemia and the excitatory effects of glycine.[119]

PRESENTATION AND TREATMENT OF HYPONATREMIA. The symptoms of hyponatremia are related to cerebral edema and increased intracranial pressure and are highly dependent on how rapidly the hyponatremia occurred. In acute onset, symptoms typically occur when Na^+ concentrations are as low as 120 to 125 mEq/L (higher in children and premenopausal females) with headache, confusion, agitation, vomiting, and lethargy. At Na^+ concentrations less than 110 mEq/L, symptoms progress to seizures and coma. In the chronic setting, clinical features may be absent even at concentrations less than 120 mEq/L. In all cases of hyponatremia, potential underlying causes such as steroid deficiency, renal disease, and cardiac disease should be identified and treated. Treatment should be tailored to the patient's intravascular volume status, the chronicity of onset, and the presence of symptoms. Chronic hyponatremia (>48 hours or of unknown duration) should be treated cautiously because of cerebral compensation for the hypoosmolar state; sudden increases in osmolality lead to cerebral water loss and osmotic demyelination (e.g., central pontine myelinolysis). Treatment options for other scenarios are listed below:

- Hypovolemic hyponatremia: Symptoms are unusual because osmotic shifts in the brain are limited by the loss of both Na^+ and water. ECF volume should be restored with isotonic saline, which will also reduce ongoing ADH release.
- Hypervolemic hyponatremia: In chronic cases, this should focus on restriction of water intake and optimization of the underlying disease state, such as improving cardiac output with angiotensin-converting enzyme (ACE) inhibitors to reduce the neurohumoral influence on water retention in cardiac failure. Loop diuretics (rather than thiazides, which impair urinary dilution) can be used to excrete free water once a negative Na^+ balance has been achieved.
- Chronic, asymptomatic hyponatremia: No immediate correction of hyponatremia is required, and the underlying cause should be treated. Fluid restriction, ADH antagonists (lithium, demeclocycline), and loop diuretics may be used.
- Symptomatic hyponatremia (typically euvolemic or hypervolemic): In patients with moderate symptoms (confusion, lethargy, nausea, and vomiting), hypertonic 3% saline may be used at an initial rate of 1 mL/kg/h with the goal of increasing $[Na^+]$ by 1 mEq/L/h for 3 to 4 hours, after which electrolytes should be rechecked. The infusion rate should be modified to ensure that $[Na^+]$ is increased by no more than 10 mEq/L in the first 24 hours of treatment. Severely symptomatic hyponatremia (coma, seizures, often with $[Na^+]$ <120 mEq/L) is typically of acute onset and the risks of undertreating are more than those of osmotic demyelination. A bolus of 100 mL of 3% saline should initially be given with the aim of acutely increasing $[Na^+]$ by 2 to 3 mEq/L. If no improvement in neurologic status occurs, this approach may be repeated once or twice at 10-minute intervals. After this, treatment should continue as for moderately symptomatic patients, with a similar goal of increasing $[Na^+]$ by no more than 10 mEq/L in the first 24 hours.[124] Electrolytes and osmolality should be rechecked every few hours, fluid balance should be carefully monitored, and patients reassessed regularly.

HYPERNATREMIA. Hypernatremia ([Na] >145 mEq/L) is less common than hyponatremia but may affect up to 10% of critically ill patients. If severe ([Na] >160 mEq/L), a 75% mortality may occur depending on the severity of the underlying disease process (Fig. 47.5).[113,114] The major mechanisms are excessive water loss with inadequate compensatory intake, lack of ADH, or administration of exogenous sodium. Diabetes insipidus (DI) is caused by a lack of ADH action as a result of impaired production or release (central DI) or reduced renal sensitivity to ADH (nephrogenic DI) with consequent failure to concentrate urine and excretion of large quantities of inappropriately dilute urine. If the patient is unable to accept compensatory fluid orally (e.g., because of coma or in the elderly with impaired thirst reflexes), they may rapidly become hypovolemic. Central DI is seen after pituitary surgery, subarachnoid hemorrhage, traumatic brain injury (particularly skull base fractures), and brainstem death. Nephrogenic DI may be due to renal disease, electrolyte disorders, or drugs (lithium, foscarnet, amphotericin B, demeclocycline).

Clinical features of hypernatremia include altered mental status, lethargy, irritability, seizures, hyperreflexia, and spasticity. Diagnosis is based on assessment of intravascular volume status, urinary osmolality, and Na^+ concentration. In patients with persistent urine output of more than 100 mL/h and hypernatremia, DI should be considered. Diagnostic criteria include an inappropriately dilute urine (<300 mOsm/kg) in combination with hypernatremia and high serum osmolality (>305 mOsm/kg). Urine specific gravity (SG) may provide a rapid guide to urine osmolality where urgent treatment is being considered; urine SG less than 1.005 in the context of hypernatremia and a potential underlying cause is consistent with DI.

Treatment is tailored to the intravascular volume status, but as with hyponatremia, correction of the Na^+ concentration should be no more rapid than 10 mEq/L/day unless the onset has been very acute.

- Hypovolemic hypernatremia: correction of the intravascular volume deficit with isotonic saline and correction of the underlying cause (e.g., insulin to reduce hyperglycemia), then correction of the water deficit with 0.45% saline, 5% dextrose, or enteral water to cover the deficit and ongoing losses.
- Euvolemic hypernatremia: use of 0.45% saline, 5% dextrose, or enteral water to replace the deficit and ongoing losses. In central DI, in which urine output is greater than 250 mL/h and risk exists for hypovolemia, titrated

intravenous doses of desmopressin acetate 0.4 to 1 µg (1-deamino-8-D-arginine vasopressin [DDAVP], an ADH analogue) should be given to reduce the urine output. Higher acute doses may have a prolonged effect with the risk for water intoxication.[113,114]

- Hypervolemic hypernatremia: stop administration of exogenous Na^+, give furosemide with 5% dextrose or enteral water. Dialysis may be indicated in the presence of renal failure.

Potassium Disorders. Because of the key role of K^+ on excitable tissue resting membrane potential, dyskalemia can lead to life-threatening cardiac arrhythmias in the perioperative period. The normally predominant intracellular distribution of K^+ means that abnormal plasma K^+ levels may reflect abnormal ECF to ICF distribution, derangements of total body K^+ content, or both. Sampling artifacts may be introduced into laboratory tests of K^+; anticoagulated samples typically give results 0.4 to 0.5 mEq/L less than those from clotted samples because of erythrocyte K^+ release during clotting. Hemolysis also artificially increases K^+ levels and may be introduced by poor sampling technique or delayed processing of samples.

HYPOKALEMIA. Hypokalemia (<3.5 mEq/L) may be caused by the conditions outlined in Table 47.7. Moderate-to-severe hypokalemia (2-2.5 mEq/L) leads to muscle weakness, electrocardiogram (ECG) abnormalities (ST segment depression, T wave depression, U wave elevation), and arrhythmias (atrial fibrillation and ventricular extrasystoles). All logic dictates that hypokalemia (e.g., as low as 2.6 mEq/L) should be associated with an increased rate of perioperative morbidity or mortality; however, no data support this conclusion.[18] Hypokalemia should be pragmatically corrected in the perioperative period to optimize neuromuscular function and reduce cardiac irritability. Such treatment is of prime importance when acute arrhythmias exist, and K^+ should be maintained at greater than 4 to 4.5 mEq/L. The speed of the infusion should be slow enough to allow equilibration throughout the entire ECF, typically no faster than 0.5 mEq/kg/h. K^+ solutions of concentration more than 40 mEq/L may be an irritant to veins and should be administered via a central venous catheter.

HYPERKALEMIA. Hyperkalemia (>5.5 mEq/L) may result from excess intake, failure of excretion, or shift from the intracellular to extracellular compartment (Table 47.8). Failure of renal secretion is mediated through impaired principal cell function in the cortical collecting duct, which depends on aldosterone-stimulated Na^+/K^+ exchange via basal Na^+/K^+ATPases and luminal Na^+ and K^+ channels. The features of hyperkalemia include muscle weakness, paralysis, and altered cardiac conduction (increased

TABLE 47.7 Causes and Mechanisms of Hypokalemia

Mechanism	Cause	Notes
Inadequate intake	Anorexia nervosa	
	Alcoholism	
	Malnutrition	
Gastrointestinal loss	Vomiting	
	Diarrhea	Especially secretory diarrhea
	Fistulas	
Excess renal loss	Mineralocorticoid excess	Primary and secondary hyperaldosteronism
	Glucocorticoid excess	High concentration of cortisol overwhelms mineralocorticoid receptor despite lower affinity
	Diuretics	Loop or thiazide diuretics deliver increased Na$^+$ load to principal cells
	Osmotic substances	Glucose, urea, and mannitol also lead to increased collecting duct Na$^+$ delivery
	Hypomagnesemia	Impairs thick ascending limb Na$^+$ reabsorption; therefore, increased distal N$^+$ delivery and K$^+$ loss via principal cells
	Renal tubular acidosis	Failure of principal cell H$^+$/K$^+$ exchange
	Bartter and Gitelman syndromes	Tubule ion transporter mutations mimicking loop or thiazide diuretic effect, respectively
Intracellular K$^+$ shift	β_2-Agonists	Also seen in sympathetic activity
	Insulin therapy	
	Acute alkalosis	
	Lithium overdose	
	Hypokalemic periodic paralysis	
	Vitamin B_{12} therapy

TABLE 47.8 Causes and Mechanisms of Hyperkalemia

Mechanism	Cause	Notes
Increased intake	Excessive K$^+$ treatment	
	Blood transfusion	Typically in patients who also have impaired excretion (i.e., severe chronic kidney disease)
	Antibiotics containing K$^+$ salts	
Failure of renal secretion	Mineralocorticoid deficiency	Hypoaldosteronism Hyporeninemic, hypoaldosteronemic state (diabetic nephropathy, tubulointerstitial disease)
	Drugs causing mineralocorticoid blockade	Spironolactone (blocks mineralocorticoid receptor) ACE-I and ARBs (reduce aldosterone production) Heparin (selective hypoaldosteronism)
	Collecting duct Na$^+$ channel blockade	Amiloride Trimethoprim Triamterene Pentamidine
	Tubulointerstitial nephritis	Cause damage or destruction of the cortical collecting duct
	Renal obstruction	
Extracellular K$^+$ shift	Succinylcholine	
	Reperfusion of ischemic tissues	Cellular ischemia reduces ATP production with failure of Na$^+$/K$^+$ATPase activity and K$^+$ "leak" to the ECF. Cell lysis further releases K$^+$. On reperfusion, excess ECF K$^+$ is rapidly delivered to the systemic circulation. During solid organ transplantation, this may be combined with residual perfusing solution used for ex vivo organ preservation, which contains a high K$^+$ content
	Insulin deficiency	
	Acute acidosis	
	Malignant hyperpyrexia	

ACE-I, Angiotensin-converting enzyme inhibitor; *ARBs,* angiotensin II receptor blockers; *ATP*, adenosine triphosphate; *ECF,* extracellular fluid.

automaticity and enhanced repolarization) with consequent ECG changes as K$^+$ levels increase[125]:

- 5.5 to 6.5 mEq/L: tall, peaked T-waves
- 6.5 to 7.5 mEq/L: prolonged PR interval
- Greater than 7.5 mEq/L: widened QRS
- Greater than 9.0 mEq/L: sine wave pattern, bradycardia, ventricular tachycardia, increased risk for cardiac arrest

Chronically induced hyperkalemia (e.g., chronic renal failure) is better tolerated than acute increases in K$^+$ concentrations. Ratios between intracellular and extracellular K$^+$ concentrations may be very abnormal with acute hyperkalemia. With chronic hyperkalemia, these ratios are probably reestablished to normal. Acute hyperkalemia sufficient to induce electrocardiographic changes is a medical emergency that requires rapid treatment. The acute treatment of hyperkalemia involves shifting K$^+$ from the ECF to ICF, antagonizing its cardiac toxicity with Ca^{2+}, and increasing renal excretion. Elimination by GI resin exchange also may be used in more chronic cases (Table 47.9). Hyperkalemia greater than 6.5 mEq/L, in the context of anuric renal failure, is an indication for acute dialysis.

Calcium Disorders

HYPOCALCEMIA. The causes of hypocalcemia are related to reduced PTH and/or vitamin D activity, increased bone deposition, Ca^{2+} chelation, or changes in binding protein concentration or ionized fraction (Table 47.10). The

TABLE 47.9 Treatments for Hyperkalemia

Mechanism	Treatment	Indication	Notes
Antagonize cardiac toxicity	$CaCl_2$ 10% (10 mL) or Calcium gluconate	K^+ >6.5 mEq/L, particularly with ECG changes	Onset of action within a few minutes, duration 30-60 min
Intracellular potassium shift	Insulin 10-20 units (administered in 50 mL 50% glucose to avoid hypoglycemia)	K^+ >6.0 mEq/L	Onset within 10-20 min, duration 4-6 h
	β_2-Agonists (e.g., nebulized albuterol 2.5 mg)		
	Hyperventilation		Induce K^+ uptake by increasing extracellular pH
	$NaHCO_3$ 1 mEq/kg	K^+ >6.5 mEq/L	
Increase renal excretion	Furosemide 20-40 mg IV	Moderate-to-severe hyperkalemia	Increases Na^+ delivery to cortical collecting duct and exchange with K^+
	Volume expansion with isotonic saline		
	Fludrocortisone		Mineralocorticoid effect
Other routes of K^+ elimination	Gastrointestinal resin exchange: sodium polystyrene sulfonate (Kayexalate) 15-30 g PO or per rectum	Any sustained hyperkalemia	
	Hemodialysis	Moderate-to-severe hyperkalemia with oliguria	

Hyperkalemia can be defined as mild (5.5-5.9 mEq/L), moderate (6.0-6.4 mEq/L) or severe (>6.5 mEq/L), with or without ECG changes.[258]
ECG, Electrocardiogram.

TABLE 47.10 Causes and Mechanisms of Hypocalcemia

Mechanism	Cause	Notes
Reduced regulatory hormones	Hypoparathyroidism	Postparathyroid or thyroid surgery. May be acute effect of reduced PTH or more long-term hypocalcemia during remineralization of bone after surgery for hyperparathyroidism ("hungry bone syndrome") Hypomagnesemia (suppresses PTH secretion)
	Pseudohypoparathyroidism	Reduced receptor response to PTH
	Reduced vitamin D activity	Hyperphosphatemia (inhibits hydroxylation—e.g., in chronic kidney disease) Dietary/sunlight deficiency Anticonvulsants (increased turnover into inactive forms)
Ca^{2+} chelation	Massive transfusion	Caused by citrate in stored red blood cell solutions
	Cell lysis	Phosphate release as a result of tumor lysis syndrome, trauma, or rhabdomyolysis
	Pancreatitis	Intraperitoneal free fatty acids formed by the action of released pancreatic lipase, which chelate Ca^{2+} salts; further contributions from coexistent hypomagnesemia and hypoalbuminemia
Increased bone deposition	Prostate, breast cancer	Increased osteoclastic activity
Reduced ionized fraction	Alkalosis	For example, acute intraoperative hyperventilation
Reduced bound Ca^{2+}	Hypoalbuminemia	Critical illness (where ionized Ca^{2+} may be normal, and Ca^{2+} replacement not required), poor nutrition
Unknown mechanism	Endotoxemic shock	

PTH, Parathyroid hormone.

following are characteristic symptoms, some of which will be absent in the anesthetized patient:

- Neuromuscular irritability
  - Circumoral and peripheral paresthesia
  - Chvostek sign (facial twitching induced by tapping on the facial nerve)
  - Trousseau sign (forearm muscular spasm induced by inflating a pressure cuff)
  - Muscle cramps
  - Laryngospasm
  - Tetany
  - Seizures
- Cardiac
  - Impaired inotropy
  - Prolonged QT
  - Ventricular fibrillation
  - Heart block

After a rapid large volume transfusion of citrate-stored blood (>1.5 mL/kg/min) or fresh frozen plasma, ionized hypocalcemia may occur as a result of citrate chelation. This may be particularly severe and prolonged in patients with hepatic impairment, in whom citrate metabolism is reduced.[126] Citrate intoxication has been described for

TABLE 47.11 Causes and Mechanisms of Hypercalcemia

Mechanism	Cause	Notes
Increased PTH	Primary hyperparathyroidism	The most common cause typically manifests with mild hypercalcemia resulting from an isolated parathyroid adenoma
	Secondary and tertiary hyperparathyroidism	The hypocalcemia of kidney disease-related hyperparathyroidism may progress to hypercalcemia with prolonged disease
Malignancy	PTH-related peptide secretion	PTH-rP may be secreted by most solid tumors; mimics PTH effects
	Osteolytic metastases	Breast, lung, lymphoma, thyroid, kidney, prostate, and multiple myeloma
	Calcitriol production	Typical in lymphoma
Excess vitamin D	Ectopic production	Granulomatous disease (e.g., sarcoid), malignancy
	Excess intake	
Decreased renal excretion	Thiazide diuretics	
Increased bone turnover	Hyperthyroidism	
	Immobilization	
Increased Ca^{2+} intake	Milk-alkali syndrome	

PTH, Parathyroid hormone; *PTH-rP,* parathyroid hormone–related peptide.

many years but is rarely a clinical problem. Although Ca^{2+} plays an important role in coagulation, coagulopathy specifically attributable to hypocalcemia only occurs at ionized Ca^{2+} concentrations less than 1.2 mEq/L (0.625 mmol/L); rather, supplemental Ca^{2+} should be given in this situation to support cardiac inotropy and neuromuscular function, aiming for ionized Ca^{2+} more than 1.8 mEq/L (0.9 mmol/L).[127] Ca^{2+} also may be given during other situations in which myocardial contractility is impaired, such as during cardiac surgery, to optimize ventricular function. After parathyroidectomy, Ca^{2+} levels should be checked frequently until they have stabilized, because Ca^{2+} and vitamin D supplementation may be required in both the short and long term. In critical illness, total Ca^{2+} levels may be reduced because of hypoalbuminemia; however, Ca^{2+} supplementation should be required only if the ionized levels are low. Ca^{2+} may be given intravenously as 10% (weight/volume) calcium gluconate or 10% (weight/volume) $CaCl_2$. Although in these formulations calcium gluconate contains less elemental Ca^{2+} (0.45 mEq/mL vs. 1.36 mEq/mL for $CaCl_2$), they are equally efficacious as long as the total Ca content given is equal. Calcium gluconate may be preferable for peripheral administration because the tissue injury from inadvertent extravasation is less severe than with $CaCl_2$. Mg^{2+} levels are often low during hypocalcemia and should also be corrected, particularly when hypocalcemia has been caused by infusion of isotonic saline or colloids in large volumes.

HYPERCALCEMIA. Hypercalcemia occurs when ECF Ca^{2+} influx from the GI tract and/or bone outweighs efflux to bone or excretion via the kidneys (Table 47.11). The symptoms are related to the severity and speed of onset of the abnormality, so mild chronic hypercalcemia is usually asymptomatic. More severe hypercalcemia manifests with neurologic symptoms (drowsiness, weakness, depression, lethargy, coma), GI symptoms (constipation, nausea, vomiting, anorexia, peptic ulcers), renal manifestations (nephrogenic diabetes insipidus—which may further aggravate hypercalcemia through dehydration—and renal stones), electrocardiographic abnormalities (shortened QT interval, prolonged PR interval), and potentiation of digoxin toxicity. Treatment should address the underlying cause, including surgical parathyroidectomy in cases of severe hyperparathyroidism, or cessation of thiazide diuretics. In addition, the treatment of symptomatic hypercalcemia should aim to increase renal Ca^{2+} excretion by volume expansion with isotonic saline and possibly loop diuretics. This combination may reduce Ca^{2+} by 1 to 3 mg/dL in 1 to 2 days.[26] Bisphosphonates enhance osteoclastic bone deposition and are given if the hypercalcemia is severe or in milder cases in which response to hydration has been inadequate. A single IV dose of pamidronate 60 mg (moderate hypercalcemia, up to 13.5 mg/dL) or 90 mg (severe hypercalcemia) should return Ca^{2+} levels to normal within 7 days, and the effect may persist for up to 1 month. Zoledronic acid is a newer bisphosphonate that may be even more effective and is given intravenously at a dose of 4 mg.[128] Bisphosphonates should only be given when clinical dehydration has been treated to avoid calcium bisphosphonate precipitation and nephrotoxicity. Glucocorticoids may also be given for hypercalcemia associated with lymphoproliferative disease or ectopic vitamin D production.[129] Calcitonin increases renal Ca^{2+} excretion and reduces bone resorption for up to 48 hours when given intramuscularly or intravenously and may contribute to a mild reduction in Ca^{2+} levels during the rehydration phase.

Magnesium Disorders

HYPOMAGNESEMIA. Serum Mg^{2+} concentration may be a poor indicator of total body content because of its large distribution in the intracellular compartment and slow equilibration with bone stores. Intraerythrocyte or intralymphocyte Mg^{2+} levels may give a better approximation of total body and tissue stores, but are more complex to process.[130,131] Both chronic and acute hypomagnesemia are associated with cardiovascular morbidity[29] and are particularly prevalent in diverse hospitalized patients (12% of general inpatients, 19% of preoperative cardiac surgery patients, 65% of critical care patients). The causes

TABLE 47.12 Causes and Mechanisms of Hypomagnesemia

Mechanism	Cause
Inadequate gastrointestinal uptake	Malnutrition Prolonged vomiting or diarrhea Intestinal fistula Pancreatitis Prolonged nasogastric suction Malabsorption syndromes Small bowel syndrome Primary intestinal hypomagnesemia
Increased renal losses	Chronic parenteral fluid therapy Hypercalcemia and hypercalciuria Osmotic diuresis Drugs: Alcohol, loop and thiazide diuretics, aminoglycosides, cisplatin, amphotericin, cyclosporin, foscarnet Phosphate depletion Hungry bone syndrome Postobstructive nephropathy Renal transplantation Polyuric phase of acute kidney injury Primary hyperparathyroidism Bartter and Gitelman syndromes

are related to reduced Mg^{2+} intake from the GI tract or increased renal losses (Table 47.12), although relative depletion may occur in times of increased cell turnover and protein production (pregnancy, athletes, cold acclimatization). The clinical presentation of hypomagnesemia may be nonspecific; symptoms often relate to common coexisting hypocalcemia or hypokalemia[32]:

- Neuromuscular: Trousseau and Chvostek signs, vertigo, seizures, weakness
- Metabolic: Carbohydrate intolerance, hyperinsulinemia, atherosclerosis
- Cardiovascular: Wide QRS, prolonged PR, T-wave inversion, ventricular arrhythmias
- Musculoskeletal: Osteoporosis and osteomalacia

Treatment should be tailored to the severity of symptoms and degree of hypomagnesemia. Asymptomatic patients with moderate-severe hypomagnesemia should receive oral supplementation, as acute IV infusions will stimulate the renal Ca^{2+}/Mg^{2+}-sensing receptor, reducing Mg^{2+} reabsorption and leading to renal excretion of much of the acute dose. In the presence of symptoms or Mg^{2+} concentration of less than 1 mg/dL, IV Mg^{2+} should be administered (initial dose of 1-2 gm over 5 to 10 minutes in the presence of seizures or acute arrhythmias).[32] Coexistent hypocalcemia, hypokalemia, or both should also be treated, but they are unlikely to improve without replenishment of Mg^{2+}. Mg^{2+} has many other therapeutic indications, even in the absence of hypomagnesemia, as outlined earlier. A few of these patients are likely to have total body Mg^{2+} depletion that has not been detected by serum Mg^{2+} levels.

HYPERMAGNESEMIA. Limited GI absorption and efficient renal excretion mean that hypermagnesemia is typically iatrogenic. Symptoms reflect the effect of Mg^{2+} on neurologic and cardiac function and relate to the serum concentration[18]:

- 5 to 7 mg/dL: Therapeutic levels in the treatment of preeclampsia
- 5 to 10 mg/dL: Impaired cardiac conduction (widened QRS, long PR), nausea
- 20 to 34 mg/dL: Sedation, reduced neuromuscular transmission with hypoventilation, reduced tendon reflexes, and muscle weakness
- 24 to 48 mg/dL: Diffuse vasodilation with hypotension, bradycardia
- 48 to 72 mg/dL: Areflexia, coma, respiratory paralysis

Mg^{2+} administration should therefore be performed with several important caveats. First, serum Mg^{2+} levels should be monitored closely during therapeutic administration. Second, because excretion is renal, doses should be decreased for patients with kidney disease. Third, it should be used with extreme caution in patients with a background impairment of neuromuscular transmission (myasthenia gravis, Lambert-Eaton myasthenic syndrome). Fourth, coadministration of neuromuscular blockers during anesthesia should be performed in reduced doses titrated to neuromuscular monitoring, because Mg^{2+} potentiates the effects of both depolarizing and nondepolarizing neuromuscular blockers. Treatment of acute hypermagnesemia includes promoting renal excretion by administration of fluids intravenously and diuresis. IV Ca^{2+} is given to temporarily antagonize Mg^{2+} and avoid diuretic-induced hypocalcemia. Definitive treatment, particularly in the presence of renal disease, may require dialysis.

Phosphate Disorders

HYPOPHOSPHATEMIA. Hypophosphatemia may be related to impaired enteral uptake, increased renal excretion, or shifts to the cellular compartment or bone (Table 47.13). Symptoms of hypophosphatemia may be precipitated by hyperventilation in patients with chronic depletion. Refeeding syndrome may be observed on commencement of enteral or parenteral nutrition after a period of prolonged starvation and may manifest postoperatively. Insulin secretion is decreased during starvation. The consequent fat and protein catabolism results in intracellular electrolyte depletion despite normal plasma levels, particularly phosphate. On refeeding, a switch back occurs to carbohydrate metabolism, increased insulin secretion, and an increased cellular uptake of PO_4^{3-}, which may lead to profound hypophosphatemia. In the most severe forms (<1.5 mg/dL), features may include rhabdomyolysis, leukocyte dysfunction, cardiac and respiratory failure, seizures, hypotension, and coma. IV PO_4^{3-} replacement carries a risk for precipitating severe hypocalcemia, so should be reserved for moderate (<2.2 mg/dL) to severe or symptomatic cases and avoided in cases of ongoing hypocalcemia. Replacement protocols should be based on patient weight and serum PO_4^{3-}.[132]

HYPERPHOSPHATEMIA. The causes of hyperphosphatemia are shown in Table 47.13. The most common cause in clinical practice is renal failure, in which the filtered PO_4^{3-} load is reduced. This may be partly compensated for in mild chronic kidney disease by increased PTH secretion and inhibition of tubular PO_4^{3-} reabsorption, but in more severe kidney disease hyperphosphatemia must be controlled with

TABLE 47.13 Causes and Mechanisms of Phosphate Abnormalities

HYPOPHOSPHATEMIA		HYPERPHOSPHATEMIA	
Mechanism	**Cause**	**Mechanism**	**Cause**
Internal redistribution	Respiratory alkalosis	Increased endogenous load	Tumor lysis syndrome
	Refeeding		Rhabdomyolysis
	Hormones (insulin, glucagon, epinephrine, cortisol)		Bowel infarction
	Sepsis		Malignant hyperthermia
	Hungry bone syndrome		Hemolysis
Increased urinary excretion	Hyperparathyroidism		Acidosis
	Disorders of vitamin D metabolism	Increased exogenous load	Intravenous infusion

oral PO_4^{3-} binders. The features of hyperphosphatemia may be related to symptomatic hypocalcemia caused by an acute elevation in PO_4^{3-} levels. Hypocalcemia is mediated via Ca^+ deposition in soft tissues when the calcium × phosphate product is elevated, and by inhibition of renal 1α-hydroxylase.[32]

Chloride Disorders. Disorders of Cl^- have the potential to affect acid-base balance, although this depends on the other constituents of the SID. As described, exogenous Cl^- administration from isotonic saline will increase the plasma Cl^- concentration with a lesser effect on Na^+ concentration, thus reducing the plasma SID and therefore pH. Conversely, disease states exemplified by both hyperchloremia and hypernatremia or by hypochloremia and hyponatremia will not affect the SID and therefore not alter pH. Many of the causes of Cl^- abnormalities (Table 47.14) are pathologic processes that also affect Na^+ levels. Investigation and treatment of these "matched" electrolyte imbalances should initially target the dysnatremia.

PRACTICAL MANAGEMENT OF PERIOPERATIVE FLUID THERAPY

At each stage in the perioperative journey, the physician must decide how much and what type of IV fluid is required. Unfortunately, a robust evidence base with answers to these questions is not always available, so a pragmatic approach based on sound physiologic knowledge and the best available evidence is required. To make the process more complicated, fluid and electrolyte requirements are a dynamic situation with great inter-individual variability. Different fluid requirements are encountered in the preoperative, intraoperative, and postoperative phases, and these vary depending on patient factors, including weight and comorbidity, and on surgical factors, such as the magnitude and site of surgery. Furthermore, the goals of fluid therapy vary depending on the severity of surgery and its associated morbidity. In "low-risk" minor surgery, fluid strategies may influence the incidence of relatively minor morbidity such as nausea and vomiting,[133,134] whereas in major surgery the focus is on the potential for fluid administration to affect postoperative morbidity, length of stay, and mortality.[111,135,136]

The goals of fluid therapy for major surgery are as follows:

- To ensure adequate circulating volume to support cellular O_2 delivery and avoid the deleterious effects of hypoperfusion on cellular function and survival, inflammation, and neurohumoral responses. This may involve manipulation of not just circulating volume but also of cardiac output and vascular resistance.
- To avoid the iatrogenic side effects of fluid administration; excessive intravascular volume (which may not be readily apparent clinically), edema, excess Na^+ or Cl^- load, toxicities related to synthetic compounds, or nonphysiologic quantities of anions (lactate, acetate, gluconate).

Large studies show that even during relatively standardized surgical procedures, there is a large variety in the volumes of fluid administered. This unexplained variability may be linked with postoperative morbidity, and regrettably appears to be more closely related to the approach of the individual anesthesia provider rather than justifiable patient or surgical factors.[107,137] A number of approaches are still being investigated in an effort to determine the optimum quantity and type of fluid that should be given in order to achieve these goals in perioperative care.

Quantity of Fluid

IV fluid quantities may be given in two main ways: (1) by estimating the requirements based on patient weight, the phase of surgery, and nature of losses to estimate the

TABLE 47.14 Causes and Mechanisms of Chloride Abnormalities

HYPOCHLOREMIA		HYPERCHLOREMIA	
Mechanism	**Cause**	**Mechanism**	**Cause**

required dose, or (2) by direct measurement of an individual's physiologic variables and administering fluid in sufficient quantities to achieve an improvement in these physiologic variables, so-called goal-directed therapy.

TABLE 47.15 The 4-2-1 Estimation of Maintenance Water Requirements

Weight	Fluid Prescription
First 10 kg	4 mL/kg/h
Second 10 kg	2 mL/kg/h
All subsequent kilograms	1 mL/kg/h

Example: A 25-kg patient would require (4 × 10) + (2 × 10) + (1 × 5) = 65 mL/h "maintenance" water.

Data from Holliday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. *Pediatrics.* 1957;19:823.

Targeting Overall Fluid Balance. Traditional approaches to perioperative fluid administration are based on historical estimates of fluid requirements during fasting (e.g., using the "4-2-1" calculation; Table 47.15[138]) and during episodes of excess loss, such as when body cavities are open or bleeding occurs. The fluid volumes prescribed are then based on perceived knowledge of the movement of fluids between compartments—for example, crystalloid being used to replace blood loss in a 3:1 ratio to account for crystalloid movement into the extravascular compartment.[18] However, much of the physiologic basis of this management approach has been questioned recently.[3,11]

An extension of the milliliter-per-kilogram approach to fluid administration has been to examine whether higher (e.g., 12-18 mL/kg/h of intraoperative crystalloid) or lower (5-7 mL/kg/h) fluid doses in the immediate perioperative phase are associated with benefit after major surgery. Unfortunately, this work has been hampered by widely varying definitions of restrictive/conservative, standard, and liberal, differing fluid types (colloids/crystalloids), and different time courses over which the fluid strategy is applied. Despite these differences, a common theme is that when fluid is given based on a milliliter-per-kilogram protocol and on clinical assessment rather than to target defined physiologic endpoints, the administration of more than 3500 to 5000 mL of crystalloid solution in the immediate perioperative period is associated with increased postoperative morbidity in contrast to administration of lower fluid volumes. This may be reflected in increased weight gain, cardiopulmonary dysfunction, impaired wound healing,[111,133] delayed GI function, and increased hospital length of stay.[139,140] One study gives apparently conflicting results,[141] although this may be partly accounted for by methodologic differences with the other studies here. In the recent pragmatic international RELIEF trial,[142] 3000 patients at increased risk for complications during major abdominal surgery were randomly assigned to receive a restrictive or liberal IV fluid regimen during and up to 24 hours after surgery. The restrictive group had a median IV fluid intake of 3.7 liters and a median weight gain of 0.3 kg as compared with 6.1 L and 1.6 kg in the liberal fluid group. There was no difference in the primary outcome of disability-free survival at 1 year, but the rates of surgical-site infection (16.5% vs. 13.6%) and renal-replacement therapy (0.9% vs. 0.3%) were increased in the restrictive group. This study provides an important warning of the consequences of excessive fluid restriction, a target for weight change after surgery (+1.5 kg), and a useful benchmark recipe.

Very few studies have robustly examined the specific effects of postoperatively administered fluid volumes. Of those tackling this area, one showed an earlier return to gut function and hospital discharge when postoperative infusions were limited to 2000 mL of water and less than 100 mEq Na^+/24 h,[108] whereas another showed no difference.[143] These represent very small studies with methodologic differences.

Although it seems likely that there exists an optimum fluid volume to be given to maximize perfusion while avoiding excessive intravascular volumes, the position of this curve likely varies widely across patients and in response to different insults. This is the rationale behind individualization of fluid therapy, where objective variables are measured and targeted with fluid therapy.

Goal-Directed Therapy. The practice of GDT is based on measuring key physiologic variables related to cardiac output or global O_2 delivery and administering fluids, and possibly inotropes, vasopressors, vasodilators, and RBCs to improved tissue perfusion and clinical outcome. This approach to fluid administration is a continuous dynamic process that targets defined physiologic endpoints rather than giving fluids without objective assessments of fluid status. GDT, used both in the perioperative and critical care setting, originated from observations that survivors of high-risk surgery achieved a particular elevation in global O_2 delivery and utilization in the perioperative period.[144] Subsequent trials used hemodynamic manipulation in an effort to replicate these supranormal "survivor values" in patients undergoing major surgery (cardiac index >4.5 L/min/m^2, O_2 delivery index (DO_2I) >600 mL/min/m^2, O_2 consumption index >170 mL/min/m^2).[145,146] The GDT approach has been studied in a wide variety of surgical settings and at various time points, including during preoperative optimization, intraoperative management, and the immediate postoperative period. Various tools to measure the physiologic targets of GDT are discussed below.

- Pulmonary artery catheter (PAC). Considered to be the gold standard hemodynamic monitor, providing measured and derived values for left-heart and right-heart filling pressures, mixed and central venous saturations, cardiac output, DO_2, and VO_2 while allowing access to the central circulation. This was the tool used in the earlier GDT trials targeting increases in cardiac index and DO_2I, but its use is declining because of concerns about catheter-associated morbidity, reduced expertise in insertion and data interpretation, and the availability of less invasive tools. In countries such as the United Kingdom, its use is typically restricted to cardiac, major liver, and transplant surgery.
- Esophageal Doppler monitor (EDM). This device uses transesophageal ultrasound measurement of descending aorta blood velocity, integrating this with estimated aortic cross-sectional area to derive SV. Other measurements include peak velocity, used as an indicator of ventricular contractility, and corrected flow time (FTc), and the duration of systolic aortic blood flow corrected for heart rate. FTc may be reduced (<330 ms) by increased systemic vascular resistance (SVR), reduced SV, or both. SVR may be calculated by inputting CVP and mean arterial pressure (MAP), helping to identify whether a low FTc is due to inadequate preload or excessive afterload. Variation in SV with positive pressure ventilation (stroke volume variation, SVV) is also measured by the latest EDM models.
- Arterial pressure and waveform analysis. These monitors analyze the invasive arterial blood pressure, continuous non-invasive blood pressure from a finger cuff, or plethysmograph trace to yield two types of measurement. First, an estimate of SV (and therefore cardiac output and index) based on the principle that pulse pressure is proportional to SV when arterial compliance is constant. Interpatient variation in arterial compliance may be accounted for by regular calibration steps using lithium dilution (LiDCO Plus, LiDCO, Lake Villa, IL) or thermodilution (PiCCO, Phillips, Andover, MA) or ignored in uncalibrated monitors (LiDCO Rapid, LiDCO; FloTrac, Edwards, Washington, DC), which represent SV trends rather than absolute estimates. Second, SVV, a predictor of fluid responsiveness based on systolic pressure variation with intermittent positive-pressure ventilation, can be measured.
- Thoracic bioimpedance, relatively underexplored in perioperative interventional trials.
- CVP: Despite one study that demonstrated improved outcomes from hip fracture surgery when CVP response to intravascular fluid challenges was compared to unmonitored control,[147] CVP readings are clearly poorly predictive of intravascular blood volume and fluid responsiveness.[148]
- Echocardiography: This advanced technique is used for guiding fluid therapy and yielding information on cardiac performance and filling, but requires operator expertise and a transesophageal approach in the intraoperative setting.
- Lactate: A reduction in elevated blood lactate concentrations is used clinically as a marker of successful resuscitation.[149]
- O_2 extraction and venous O_2 saturation (SvO_2) or central venous saturation ($ScvO_2$): Inadequate tissue O_2 delivery may be signaled by increased O_2 extraction and the resultant mixed or central venous O_2 desaturation. Low $ScvO_2$ is associated with poor outcomes after high-risk surgery,[150] although it has been targeted in only one interventional study in major noncardiac surgery.[151]

A typical approach to GDT is to rapidly administer 250 mL boluses of colloid or crystalloid, aiming to increase SV by 10% or more each time. This process is continued until there is no further rise in SV, at which point ventricular filling is taken to be on the flatter part of the Starling curve. One example is in Fig. 47.6. Trials have varied in terms of the period during which this intervention is used (intraoperative or intra- and postoperative) and whether fluid loading is combined with protocolized inotrope infusion. Recent meta-analyses have highlighted the potential benefits of the GDT process. One meta-analysis with the most

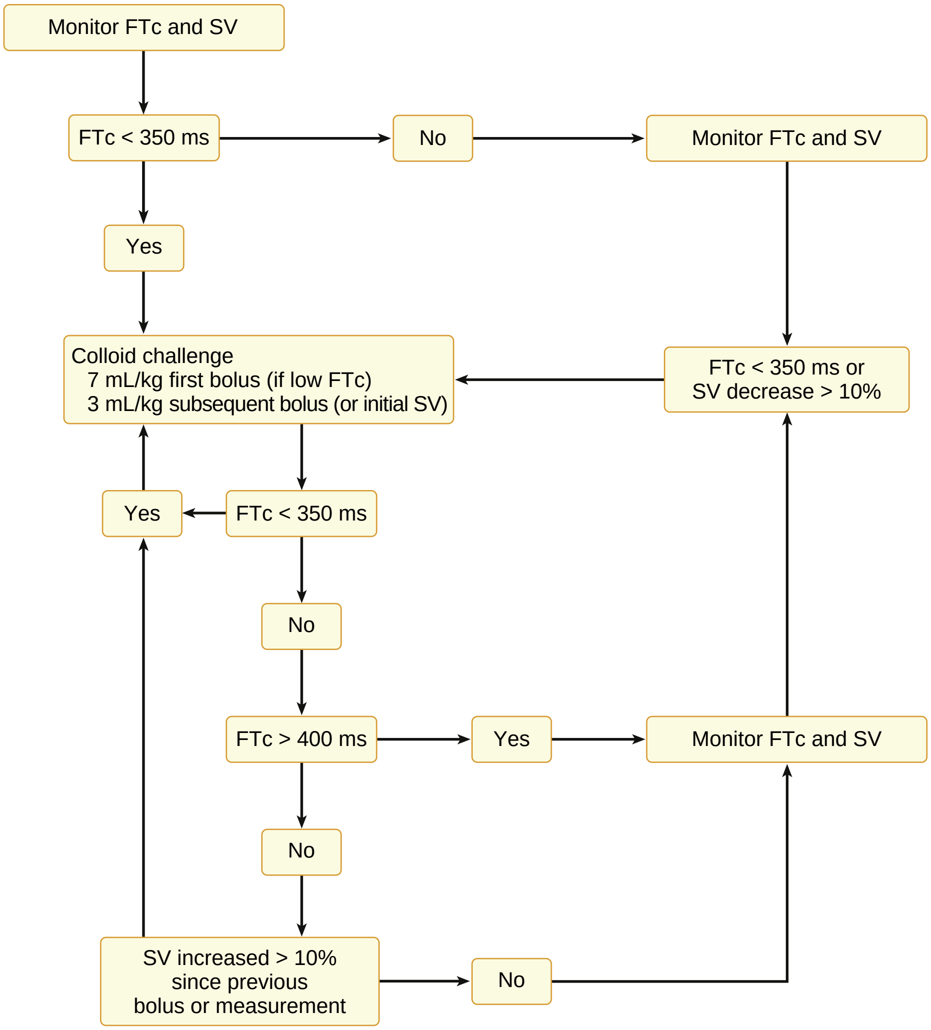

Fig. 47.6 Protocol for EDM-based intraoperative goal-directed fluid therapy. *FTc,* Heart rate-corrected descending aorta flow time; *SV,* stroke volume. (Redrawn from Noblett SE, Snowden CP, Shenton BK, et al. Randomized clinical trial assessing the effect of Doppler-optimized fluid management on outcome after elective colorectal resection. *Br J Surg.* 2006;93:1069.)

tightly defined patient group (surgery but not trauma or sepsis) and all time points (preoperative, intraoperative, and postoperative GDT) and GDT tools (PAC, EDM, and arterial waveform analysis), showed GDT to be associated with a reduction in postoperative morbidity and hospital length of stay.[136] Specifically, GDT leads to a reduction in the number of patients with postoperative renal impairment, respiratory failure, and postoperative wound infection. Many of the individual studies were not powered to detect a mortality difference; however, when analyzed rigorously in this Cochrane systematic review, excluding poorly controlled studies, hospital or 28-day mortality was reduced by GDT.[136]

The lack of more contemporary trials of adequate size to detect important outcome differences has been addressed in recent years. An increasing number of large, pragmatic clinical effectiveness trials using minimally invasive arterial waveform or Doppler devices have been completed or are in progress. Although the results of individual trials are mixed, most results appear to agree with the potential benefit of using these monitors in elective surgery suggested by the previous Cochrane meta-analysis.[152–154] Large trials aiming to give a definitive answer on this intervention are currently underway in both elective and emergency gastrointestinal surgery.

A frequent finding in GDT studies is that the intervention group receives more fluid, typically an extra 500 mL of colloid, a finding that has raised questions, as follows:

- This fluid excess may seem to be at odds with the potential benefits of a conservative fluid strategy. However, it should be noted that the fluid excess in the liberal groups of fluid balance studies is typically of greater magnitude and different type (~1500 mL of excess crystalloid overall) and is indiscriminate, in comparison to the targeted administration to some patients based on specific physiologic variables in GDT. This difference may be partly responsible for the finding that overall outcomes in “liberal” groups are worse than those in GDT groups in their respective trials.[112]
- The potential benefit of the GDT process is underlined by a failure to replicate the improved outcomes when these

fluid balance differences are used as therapeutic targets. This was shown in a study in which the intervention group subjects were uniformly administered an extra 500 mL of colloid compared with the control group, with no improvement in postoperative outcomes.[155] This suggests that it is the individualization of therapy supported by monitored variables that may bring the clinical benefit.

- Even in GDT trials with few overall differences in intravascular fluid balance between the control and intervention groups, the individualization of patient fluid requirements may be reflected in the timing of intraoperative fluid administration. In one study, early intraoperative EDM-guided fluid administration in the first quarter of surgery increased cardiac output above that of the control group, a difference that was sustained until the end of surgery and reduced postoperative morbidity.[156]

Despite the apparent benefit of GDT in the studies performed so far, further research is still required in large-scale multicenter trials to address the following:

- Although most of the GDT studies have used boluses of a variety of colloids, it is not clear if one colloid is superior or whether crystalloids could be used for boluses instead. This is particularly relevant given the cost and potential toxicities of colloids when examined in sufficiently powered studies in critical care populations.[51,84,157]
- Hemodynamic monitors are currently under rapid development, and newer devices should be compared with existing ones for their utility in guiding GDT. Ultimately, as newer technologies are evaluated, the potential benefits of GDT may relate to the process of administering fluids based on rational physiologic endpoints rather than to the specific GDT tool used. As previous evaluations of monitoring devices have shown, no benefit is gained from using a device per se, but rather from the therapeutic intervention that the device allows.[158]

Appropriate Fluid Selection

Crystalloids or Colloids for Intravascular Plasma Volume Expansion. Although crystalloids are the most rational choice of fluid for replacement of evaporative losses, maintenance fluid requirements, and expansion of the entire extracellular fluid volume, the choice of crystalloid or colloid for plasma volume replacement in the perioperative phase is not clear. This underlines the lack of adequately powered perioperative studies directly comparing the two fluid types when administered in a similar fashion. Although most GDT studies use colloid for their intravascular volume expansion, these studies are also comparisons of fluid administration guided by physiologic endpoints with nonguided therapy. Whether the same level of benefit can be achieved by crystalloid-based GDT merits further investigation. Crystalloid may be effective in plasma volume expansion (PVE) at amounts less than previously reported, although typically 40% to 50% more crystalloid than colloid must be administered to obtain the same clinical volume effect.[3] When combined with the increased propensity of crystalloid to filter across the capillary membrane, more extravascular volume expansion occurs, potentially causing tissue edema. When compared with colloids, crystalloids may lead to increased GI mucosal edema[159] and the potential for delayed postoperative GI function and bacterial translocation. The differential effect of crystalloids when compared to colloids on tissue O_2 tension has no clear consensus.[52] The limited data comparing colloid with crystalloid for perioperative PVE may lead clinicians to extrapolate findings from studies in critical care. A Cochrane review highlighted the lack of improvement in all-cause mortality when colloids were used for intravascular volume expansion in unselected critical care populations.[160] In studies specific to patients with sepsis, starch-based colloids, including smaller MW versions, are associated with an increased requirement for renal replacement therapy, blood transfusion, and an increase in severe adverse events.[83] These data should be interpreted cautiously. First, some critical care studies compared starches with saline in the control group, which may itself be associated with renal problems.[51] Second, the surgical population has a different physiologic phenotype to those in critical care; meta-analysis suggests that starch is not associated with excess mortality or kidney injury in surgical patients, although the available trials are limited.[86] Despite these limitations, it is reasonable to avoid starch colloids in perioperative patients with severe sepsis or at increased risk of renal failure, pending the necessary large-scale trials assessing their safety in the perioperative setting. This is reflected in license restrictions for these fluids in the United States. In the United Kingdom, the use of starches has been suspended in all settings. The potential toxicities of colloids must be weighed against the potential fluid overloading effects of PVE using crystalloids until more data are available informing the debate on crystalloids versus colloids for perioperative PVE.

Saline-Based or Balanced Solutions

TYPICAL PRACTICAL APPROACH. The following suggestions represent an assimilation of the physiology, fluid pharmacology, and available evidence presented in this chapter. However, in many areas of perioperative fluid management, the lack of robust evidence means that the choice of fluid and method of administration remains a clinician's choice informed by the balance of risks and benefits. The overall themes in prescribing fluids in moderate-to-major surgery are:

- The indication for giving a specific fluid should always be considered. Pure "maintenance" fluid should be given at a low fixed rate, with fluid required for replacement of losses or for resuscitation considered separately.
- Fluids administered should be individualized. This may be as simple as dosing postoperative maintenance fluids on a milliliter-per-kilogram basis or titrating intraoperative plasma volume expansion to objectively measured physiologic variables.
- Fluid status changes constantly throughout the perioperative period and should be frequently reassessed.
- The approach should be adapted to the patient and surgical factors outlined later.

Preoperative. In preparing for elective surgery, oral clear fluid intake should continue until 2 hours preoperatively and longer fasting discouraged. The use of preoperative bowel preparation should be restricted to carefully selected cases, and in these cases an infusion of 1 to 2 L of balanced crystalloid with K^+ supplementation should be given in the preoperative period. Chronic comorbidities should be assessed for their influence on fluid and electrolyte balance, as outlined later.

Emergency surgery patients are likely to have acute disturbances of fluid compartments. They require timely resuscitation guided by rational physiologic endpoints such as trends in blood pressure and heart rate, lactate, urine output, and mixed or central venous O_2 saturations. Although preoperative fluid administration using cardiac output monitoring makes clinical sense, often logistical implications are involved with this approach and in some cases (ongoing blood loss or early surgical control of sepsis) surgery should not be delayed. A pragmatic approach is required to provide ongoing fluid resuscitation without compromising early surgical intervention. Upper GI losses should be quantified and replaced with isotonic saline, and lower GI losses (fistula, ileus, or obstruction) with balanced crystalloid. K^+ should be supplemented as appropriate.

Intraoperative. A low background infusion (e.g., 1-1.5 mL/kg/h) of crystalloid should be used for maintenance requirements during surgery. Hypotension caused by general or regional anesthesia is related primarily to vasodilation and reduced inotropy, and unless the patient is hypovolemic because of preoperative factors, it is more rational to treat this with small doses of vasopressors and/or inotropes.[11] Fluid therapy in patients considered to be at higher risk should be guided by invasive pressure monitoring to allow for early recognition of overt hypovolemia and global tissue perfusion. Although no universally accepted definitions of a high-risk case exist,[161] factors such as major elective or emergency surgery, advanced age, comorbidities, and poor exercise tolerance, increase postoperative mortality risk to greater than 5%. In these cases and particularly in certain orthopedic and intraabdominal operations, where the evidence is strongest, cardiac output should be optimized by titrating boluses of a suitable colloid or balanced crystalloid to a measured variable such as SV and FTc, or cardiac output and O_2 delivery. Stroke volume variation may also be measured, although its ability to accurately predict fluid responsiveness may be limited.[162] Blood loss should be replaced with colloid or blood products depending on the volume lost and variables suggesting inadequate tissue O_2 delivery. Crystalloid may be used as an alternative for intravascular plasma volume expansion, but the increased volume required and potential for extravascular volume expansion should be considered. Overall, the goal should be to achieve euvolemia by the end of surgery or the early postoperative period.

Postoperative. High-risk surgical patients may benefit from an ongoing period of GDT targeting O_2 delivery in the early postoperative period.[163] In all other patients after major surgery, an assessment of fluid status should be made based on clinical examination and supporting physiologic measurements such as lactate, central or mixed venous saturations, and cardiac output variables, if available. If patients are euvolemic and able to return to oral fluid intake, this is the best way of avoiding the iatrogenic effects of postoperative fluid administration. Early oral intake is typically well tolerated and safe, and early oral nutrition may reduce the incidence of postoperative complications.[164]

The following should be done in patients requiring ongoing IV therapy:

- Electrolytes should be checked at least daily to monitor for hyponatremia and other electrolyte derangements.
- Fluid requirements should be strictly divided into three categories for their ongoing assessment and treatment
  - **"Pure" maintenance requirements.** These should be salt-poor and contain a modest volume of free water to account for the postoperative state of salt and water retention. Infusions should therefore consist of the following[164]: (1) 1500 to 2500 mL in 24 hours, depending on weight, or 1 to 1.2 mL/kg/h. Given the relative reduction in TBW in obesity (see previous discussions on crystalloids, fluid compartments), consideration should be given to dosing this fluid requirement based on ideal body weight in this setting. (2) 50 to 100 mEq Na^+ should be given in 24 hours, and (3) 40 to 80 mEq K^+ should be given in 24 hours.
  - It is likely that part of this minimal maintenance volume should comprise hypotonic fluids such as 5% dextrose or 0.18% saline with 4% dextrose. Because of the risk for postoperative hyponatremia, this maintenance intravascular fluid volume should not be increased if suspicion for hypovolemia exists. Rather, the source of the ongoing loss should be identified and treated separately. As oral fluid intake increases, this maintenance fluid should be reduced proportionately.
  - **Replacement of ongoing losses.** This fluid requirement requires frequent reassessment to appropriately titrate replacement fluids. Volumes given should reflect measured amounts lost and an assessment of intravascular volume status and adequacy of organ perfusion (mental state, lactate, hemodynamic trends). Losses from the GI tract (vomiting, nasogastric aspirates, stoma) should be replaced with an equal volume of isotonic saline or balanced crystalloid with K^+ as appropriate. Losses to third spaces, such as reaccumulation of ascites, should be treated with a mixture of colloid and crystalloid, and blood loss replaced with colloid, blood, or blood products.
  - **New requirements (resuscitation).** New requirements may relate to the development of postoperative complications such as hemorrhage (absolute hypovolemia) or acute sepsis (relative or absolute hypovolemia).

Postoperative oliguria should be interpreted cautiously, particularly in the first postoperative day. The patient should be carefully assessed for corroborative evidence of impaired end-organ perfusion and alternative causes of oliguria, including catheter obstruction and intraabdominal hypertension. In the absence of markers indicating hypovolemia and inadequate tissue perfusion, large volumes of fluid challenge are inappropriate and may aggravate postoperative positive fluid and Na^+ balance in the face of a normal surgical stress response.

Special Considerations

Patient Factors

Heart failure. The diverse pathophysiologic effects of heart failure and their treatment may make perioperative fluid management particularly challenging. The hemodynamic effects of chronic heart failure are characterized by systolic and diastolic dysfunction of the left, right, or both ventricles with secondary maladaptive neurohumoral responses. These include persistent activation of the RAA axis, with consequent salt and water retention, and chronic sympathetic nervous system (SNS) activation, with persistent tachycardia and vasoconstriction. Undertreated patients may therefore present with edema in lungs and peripheral tissues and increased central blood volume in the face of poor myocardial function.

Treatments for heart failure attempt to correct many of the neurohumoral responses, and many have been shown to improve long-term prognosis in heart failure. In the perioperative phase, they may bring challenges to fluid management, including chronic volume depletion, blunting of normal sympathetic responses, and electrolyte disturbances. They include β-adrenoreceptor antagonists, diuretics, digoxin, and antagonists of aldosterone and angiotensin.

Perioperative fluid therapy in patients with heart failure has two goals. The first is to preserve cardiac output, bearing in mind the influence of preload, contractility, and afterload. The ventricles are typically poorly compliant and require adequate preload, which may be reflected in a relatively high CVP and adequate diastolic filling time to maintain good cardiac output. However, the flattened Starling curve of the failing heart means that excessive intravascular volume infusion and preload may lead to impaired contractility and worsening cardiac output. This leads to "forward failure," manifested as inadequate organ perfusion, and "backward failure," manifested as pulmonary and peripheral edema, particularly in the presence of aberrant salt and water excretion. The second goal is to minimize the cardiac work to avoid a vicious cycle of increased cardiac O_2 demand, inadequate O_2 supply, and worsening myocardial function. In particular, tachycardia triggered by hypovolemia and other stimuli should be avoided. Striking a balance between hypovolemia and hypervolemia is particularly important in patients with heart failure, but it may be difficult to assess clinically.

The practical approach to patients with heart failure involves careful preoperative assessment of fluid status and electrolytes and optimization of heart failure treatments when time allows. The complex cardiovascular situation often requires cardiac output monitoring for moderate or major surgery. Invasive modalities include transesophageal echocardiography or pulmonary artery catheterization,[165] although less invasive modalities may also be helpful. Measurement of cardiac filling and contractility is particularly important because the sources of intraoperative hypotension (reduced preload, contractility, or afterload) require different treatments. Infusion of large volumes of any fluid, including blood and products, should be undertaken only with objective evidence of intravascular volume loss.

The effects of heart failure therapies should be evaluated carefully in the perioperative phase. Diuretics may leave patients in a chronically volume-contracted state that worsens anesthesia-related hypotension. Loop diuretics frequently cause hypokalemia and hypomagnesemia, whereas aldosterone antagonists cause hyperkalemia, which may be severe when combined with ACE-inhibitor treatment or chronic kidney disease. Normalization of electrolytes is particularly important in patients taking digoxin, in whom hypokalemia may potentiate digoxin toxicity. ACE-inhibitors or angiotensin receptor antagonists themselves lead to a blunted sympathetic and angiotensin response to anesthesia-related vasodilation. The hypotension caused by these should be treated appropriately by small doses of inotropes or vasopressors, which may include vasopressin analogs.[165]

Kidney disease. Patients with dialysis-dependent chronic kidney disease have multiple pathologic features that must be considered in perioperative fluid therapy. Overall fluid balance may be disturbed by reduced or absent native urine production, with reliance on dialysis to achieve the target "dry" weight, representing estimated euvolemia. Organ O_2 delivery may be impaired by various factors, including chronic anemia, endothelial dysfunction, and microvascular perfusion abnormalities. The frequent coexistence of heart failure and systemic or pulmonary hypertension and the bleeding tendency caused by platelet dysfunction further increase the perioperative risk.[166]

Preoperative assessment should focus on the adequacy of chronic dialysis in attaining euvolemia and estimating the normal volume of native urine output. Comorbidities should be assessed and optimized. Surgery should be undertaken in a facility where preoperative and postoperative dialysis or hemofiltration can be offered in case of intraoperative fluid overload or hyperkalemia. In elective surgery, preoperative dialysis should be timed such that the patient enters the intraoperative phase with a normal blood volume. Surgery in the presence of hypervolemia increases the risk for pulmonary and peripheral edema, hypertension, and poor wound healing, whereas hypovolemia increases the risk for anesthesia-related hypotension and inadequate tissue perfusion. Practically, this means performing dialysis the day before surgery to allow for equilibration of fluid and electrolyte compartments and time for dialysis anticoagulants to be metabolized. Electrolytes should be checked on the morning of surgery; sampling too soon after dialysis, before equilibration, may give an artificially low K^+ result leading to unnecessary exogenous supplementation. Conversely, fasting may actually favor a hyperkalemic state as a result of the reduced presence of insulin; the ideal K^+ value after dialysis is in the low-to-normal range. For emergency surgery, there may not be sufficient time to safely dialyze patients preoperatively. In this case, electrolyte abnormalities must be managed conservatively, with particular care paid to intraoperative fluid balance.

As with other major comorbidities with a critical impact on fluid and electrolyte balance, the importance of avoiding both hypovolemia and hypervolemia and the predisposition to inadequate tissue perfusion mean that detailed monitoring of hemodynamic variables, including invasive central venous and arterial pressure and cardiac output, should be considered for moderate-to-major surgery. The amount of fluid administered intraoperatively should be titrated to objective physiologic measurements, although the type of fluid given is open to debate. Large volumes of isotonic saline should be avoided, because the induced acidosis favors extrusion of K^+ from cells. In contrast, K^+-containing balanced crystalloids did not cause hyperkalemia in clinical trials.[44,167] An alternative crystalloid is a K^+-free HCO_3^--buffered dialysis solution such as Hemosol. Colloids may be used for intravascular volume replacement, although owing to their predominantly renal excretion, the volume effect and potential toxicities may be exaggerated in these patients. Liaising with the nephrologist is important before considering blood transfusion; if the patient is awaiting renal transplantation, human leukocyte antigen-matched blood may be required to minimize antibody formation and future difficulties with blood and tissue matching.

UPPER GASTROINTESTINAL LOSS. Large volume gastric fluid loss may be caused by congenital or acquired gastric outlet obstruction and lead to a distinct pattern of fluid and acid-base abnormalities. Dehydration occurs as a result of water loss, reduced total body Cl^- content, and alkalosis caused by proton loss, with raised serum HCO_3^-. The initial renal response is formation of urine with low Cl^- and high HCO_3^- content. However, progressive dehydration leads to increased aldosterone secretion, aimed at retaining Na^+ and water. Na^+ is retained at the expense of K^+ and H^+ ions, leading to hypokalemia, and worsening metabolic alkalosis with a paradoxically acid urine. The alkalosis also reduces the circulating ionized fraction of Ca^{2+}.

Correction should include gradual rehydration with isotonic saline and K^+ supplementation, changing to dextrose-containing saline solutions depending on electrolyte analysis. Any surgery required to treat gastric outlet obstruction should be scheduled after correction of the volume and acid-base status.

SEPSIS AND ACUTE LUNG INJURY. Patients with infection and sepsis syndromes may be encountered early in their presentations, as surgical source control of infection (drainage of abscesses, debridement of necrotic tissues, removal of infected devices) forms a key part of early sepsis therapy.[168] Cardiovascular instability may be a particular problem, contributed to by endothelial dysfunction and intravascular fluid loss, vasodilation with fluid maldistribution, sympathetic redistribution of blood volume away from the peripheral circulation, and impairment of cardiac function. Fluid resuscitation, with the goal of maintaining adequate end organ perfusion, has historically been a key part of the first six hours of sepsis treatment, which may represent the perioperative period for some patients. Early trials suggested that protocolized fluid resuscitation targeting central venous oxygen saturation was more effective than resuscitation guided by only CVP, MAP, and urine output targets in reducing mortality from sepsis.[169] However, more recent large international trials have shown that this approach has similar outcomes to resuscitation based on standard or protocolized care without targeting central venous oxygen saturations.[170-172] The following approach is suggested for septic patients with evidence of tissue hypoperfusion:[173]

- At least 30 mL/kg of crystalloid should be given within the first three hours of resuscitation.
- Further fluids should be guided by frequent reassessment of hemodynamic status. This assessment may incorporate more detailed measurements such as cardiac output, in addition to routinely available physiological variables (heart rate, blood pressure, urine output).
- Dynamic tests of fluid responsiveness such as passive leg raise or stroke volume response to a fluid challenge are recommended over static targets such as a fixed CVP value.
- Other resuscitation targets may include a MAP >65 mm Hg in those requiring vasopressors, and normalization of lactate in patients with elevated levels.

These guidelines are based on a limited evidence base and further research is needed to refine this area. For example, some trials have suggested that a fluid bolus strategy may not be helpful in attaining hemodynamic targets[174] or may even be harmful in some settings.[175]

In established sepsis, fluid management becomes even more challenging due to the frequent presence of microvascular dysfunction, extravascular fluid overload, and disturbed neurohumoral responses to variations in intravascular volume.[176] There is uncoupling of the O_2 delivery and consumption relationship as a result of cellular inability to use O_2 (cytopathic hypoxia).[177,178] Because of this uncoupling, strategies to elevate global O_2 delivery may be of little benefit while exposing patients to potential side effects of excessive fluid and catecholamine administration.[179,180] At this stage, a less positive overall fluid balance is associated with improved outcomes.[181]

Patients with established acute respiratory distress syndrome (ARDS) may also present for surgical procedures. Here the focus of fluid therapy is the fine balance between avoiding an increase in lung edema while maintaining adequate tissue perfusion. ARDS is typified by increased pulmonary endothelial permeability, with extravasation of water and protein. The consequences are interstitial and alveolar edema, reduced pulmonary compliance, increased pulmonary artery pressures, and hypoxemia. Meanwhile, organ perfusion may be impaired by increased intrathoracic pressures and reduced cardiac filling pressures. Observational studies have highlighted an association between overall positive fluid balance and mortality in ARDS,[182] backed by a large randomized controlled trial demonstrating a reduction in ventilator and intensive therapy unit days in patients treated with a conservative fluid administration strategy.[183] The findings were similar in a subgroup of patients from this trial who had undergone surgery and were treated with lower fluid volumes. There was also no increased kidney injury seen in the low fluid volume group.[184] Extravascular lung water (EVLW) seems to be important in predicting the worse outcomes associated with a more positive fluid balance. Thermodilution studies showed excess EVLW to have reasonable sensitivity and specificity in predicting ICU mortality in patients with ARDS.[185] Assuming global organ perfusion appears adequate, as demonstrated by normal lactate levels, intraoperative losses should be replaced but otherwise be conservative in the volumes of fluid given to patients with ARDS intraoperatively. There is a lack of adequately powered studies on the choice of colloid or crystalloid for intravascular volume replacement in patients with ARDS.

Burns. Extensive burns create a situation of copious fluid loss from the circulation combined with particular sensitivity to the effects of excess fluid administration. Thermal injury creates an area of necrotic tissue with surrounding ischemic areas. The combination of dead tissue with areas undergoing ischemia and subsequent reperfusion causes localized and systemic inflammatory reactions through histamine, prostaglandin, reactive O_2 species, and cytokine release. Local impairment of endothelial barrier function leads to the loss of oncotically active plasma constituents, increased capillary filtration into the interstitial compartment, and evaporative transcutaneous fluid loss as a result of loss of skin integrity. Through similar mechanisms, extensive burns may lead to the systemic inflammatory response syndrome, with its well-recognized effects on fluid compartments outlined previously. The deleterious role of this inflammatory response is underlined by the reduction in mortality seen with early burn excision compared with conservative care.[186] IV fluid therapy is generally instituted for burns of greater than 15% total body surface area in adults and 10% total body surface area in children.[187] However, increasing uncertainty exists about the volume and type of fluid that should be given to patients with burns. Fluid administration is largely still based on formulas such as the Parkland formula (Box 47.1) or the Muir and Barclay versions. Although these have given a starting point for resuscitation volumes based on patient weight and extent of burn, myriad other patient and pathologic factors put such a recipe-based approach at odds with modern perioperative fluid therapy based on objective physiologic goals. Although the approaches based on these formulas advocate down-titration of administered fluid volumes if urine output is adequate (0.5-1 mL/kg/h),[188] in reality this appears not to be practiced. Indeed, large studies have shown that the majority of burn patients receive fluid volumes in excess of those predicted by the Parkland formula, with a mean of 6 mL/kg/% burn compared with 4 mL/kg/% burn in 24 hours predicted by the formula.[189] Conversely, patients with inhaled and other nonburn injuries, electrical burns, or delayed resuscitation are considered to need increased resuscitation intravascular volumes, yet this is not taken into account by the formulas.

Excessive fluid administration in burned patients ("fluid creep") is not benign. As in all conditions typified by systemic inflammation, excess administered fluid will collect in compliant compartments. Pulmonary edema requiring ventilatory support, fasciotomies in muscle compartments, raised intraocular pressure, and conversion of superficial to deep burns have been observed and attributed to fluid resuscitation.[187] Intraabdominal hypertension and compartment syndrome are correlated to the volume of fluid administered, with a particular rise when more than 300 mL/kg is administered in 24 hours.[190] These concerns have led to renewed efforts to find the optimum regimen for burn resuscitation in terms of crystalloid versus colloid, newer formulas using lower volumes such as the Haifa formula, and targeting objective physiologic parameters such as SV or intrathoracic blood volume. Early trials have suggested that minimally invasive cardiac output monitoring may have a role, although there are no adequately sized trials to show whether this approach improves outcomes.[191] Pending a consensus from this ongoing work, burn resuscitation should be commenced with one of the currently accepted formulas, but actively down-titrated if a urine output of 0.5 to 1 mL/kg/h is obtained. A combination of crystalloids and colloids may be used to reduce the total fluid volume administered,[192] although the early use of colloids is controversial due to the perceived risk of extravasation of oncotically active molecules in the presence of severe capillary leak. In addition, patients with burns were included in recent license restrictions on the use of starches.[191] Intraabdominal pressure should be monitored, and consideration given to assessing resuscitation endpoints, such as lactate and cardiac output, in addition to urine output.

BOX 47.1 Parkland Burn Fluid Resuscitation Formula

First 8 h: 2 mL/kg × % TBSA (lactated Ringer solution)
Next 16 h: 2 mL/kg × %TBSA (lactated Ringer solution)
Next 24 h: 0.8 mL/kg × %TBSA (5% dextrose) + 0.015 mL/kg × %TBSA (5% albumin)

%TBSA, Burn size as % of total body surface area. Time periods refer to the time since the burn occurred.

Data from Baxter CR. Problems and complications of burn shock resuscitation. *Surg Clin North Am.* 1978;58:1313.

Pediatrics. Perioperative fluid therapy in pediatric patients has for many years been based on traditional approaches that are increasingly being reexamined. Holliday and Segar[138] proposed a quantity and composition of maintenance fluid in hospitalized children in 1957 based on water requirements to sustain average metabolic activity and the electrolyte composition of milk. This developed into the 4-2-1 volume calculation for maintenance fluid requirements aimed at replacing insensible and urinary losses with hypotonic crystalloids containing glucose to maintain isoosmolality. These concepts were translated into the perioperative phase and glucose-based solutions were administered intraoperatively to reduce the apparently high risk for preoperative hypoglycemia after prolonged fasting,[193] and postoperative maintenance fluids were prescribed based on the 4-2-1 calculation using hypotonic crystalloids. Furthermore, the pediatric population was thought to be at risk for clinically significant preoperative dehydration by fasting, as a result of limited urinary concentrating ability and ongoing insensible losses because of the relatively large body surface area. Intraoperative replenishment of these volumes using 25 mL/kg of isotonic salt solution for those 3 years of age and younger or 15 mL/kg for those 4 years of age and older has been recommended.[194]

Multiple factors have led to a reevaluation of this approach. First, the modern approach to preoperative fasting, such that children may take clear—and potentially carbohydrate-containing—fluids up to 2 hours before surgery, reduces the risk for hemodynamically significant preoperative dehydration.[195] Second, the incidence of preoperative hypoglycemia is infrequent (<2.5%) and related to inappropriately prolonged fasting or other risk factors, such as prematurity, small for gestational age, or poor nutritional status.[196,197] Surgery itself increases blood glucose concentration, and administering glucose-containing solutions intraoperatively may cause hyperglycemia,[198] with the potential for osmotic diuresis and electrolyte abnormalities, or even adverse neurologic outcomes in the event of an ischemic or hypoxic event.[197] Glucose-free balanced crystalloid solutions should therefore be used intraoperatively, except in those at particularly high risk for hypoglycemia. Third, increasing awareness of the incidence and potentially disastrous neurologic outcomes from postoperative hyponatremia in pediatric populations has led to a reappraisal of postoperative hypotonic crystalloid maintenance fluids in 4-2-1 volumes. The effective SIADH induced by surgical stress and aggravated by the presence of pain and hypovolemia causes water retention and the risk for hypoosmolar hyponatremia if hypotonic solutions continue to be infused in significant volumes. Proposed strategies to avoid this include using one half to two thirds of the calculated 4-2-1 formula for maintenance fluids,[195] avoiding the most hypotonic fluids (4% dextrose with 0.18% NaCl),[197] using balanced isotonic crystalloids (containing glucose if available).[199,200] General measures that should be applied to all patients include:

- returning to oral fluids as early as possible
- ensuring euvolemia to minimize the ADH response[201]
- clearly dividing *maintenance* requirements from the variable amounts of fluid required because of *ongoing losses* (e.g., GI or blood), which should typically be replaced by isotonic crystalloids, colloids, or blood
- checking electrolytes at least daily in those still receiving IV fluids

Although isotonic saline has been advocated as a “safer” fluid for postoperative maintenance, this brings the risk for Na^+ overload and hyperchloremic acidosis.

More recent developments in perioperative fluid management remain underexplored in pediatric populations. In particular, there is little data on whether colloid volume expansion is beneficial or harmful in pediatrics when compared with crystalloids, or whether goal-directed fluid therapy may confer the advantages that have been suggested in adult populations.

HEPATIC FAILURE. Progressive liver disease and cirrhosis cause a distinctive pattern of abnormal fluid balance. The combination of peripheral vasodilation and relative intravascular depletion can mimic a decrease in intravascular volume. Yet, total body Na^+ and water are retained with ascites and edema.[202]

The widely accepted pathophysiologic mechanisms are that progressive disruption of liver architecture combines with decreased hepatic nitric oxide (NO) bioavailability and increased vasoconstrictor production, leading to sinusoidal hypertension. Compensatory vasodilatory mechanisms, including NO overproduction, lead to splanchnic and systemic vasodilation, relative hypovolemia, and reduced systemic arterial pressure. This triggers baroreceptor-mediated activation of the RAA, SNS, and ADH release. Although cardiac output increases, reduced systemic vascular resistance persists despite these compensatory mechanisms. The state of hyperaldosteronism causes salt and water retention, but hyponatremia occurs because of a relative excess of water retention. Splanchnic vasodilation and vascular permeability combine with decreased lymphatic drainage to favor the formation of ascites. The neurohumoral response also induces renal artery vasoconstriction, reducing renal blood flow and increasing the risk for hepatorenal syndrome. A range of therapies to maintain patients in a compensated state include: dietary fluid and salt restriction, diuretics (particularly spironolactone and loop diuretics), and intermittent or continuous drainage of ascites. However, the perioperative period presents considerable potential for disturbance of this fine balance. Excessive administration of isotonic saline will aggravate the preexisting salt and water overload, leading to further ascites and edema formation. Conversely, periods of hypovolemia are poorly tolerated, leading to a significant deficit in organ perfusion, further stimulation of the RAA, SNS, and ADH axes, and increasing risk for kidney injury. The approach should therefore be to assess volume status carefully, considering cardiac output monitoring, and to replace losses with appropriate volumes of isotonic crystalloid, colloid, or blood but to avoid salt and water overload. In instances of large-volume (>6 L) paracentesis, hemodynamic instability is a risk. Albumin appears to be a more effective prophylactic treatment for this than saline, abrogating the stimulated increase in plasma renin activity and maintaining more stable hemodynamics.[203] Lactate and other buffered fluids may be used in hepatic failure, although their metabolism may be slowed in advanced liver disease.

In decompensated liver disease with encephalopathy, raised intracranial pressure may be present and osmotherapy, such as hypertonic saline, should be used to bring plasma Na^+ into the high-normal range.[204] This is in contrast to chronic compensated liver disease, in which a degree of hyponatremia is well tolerated and does not require acute correction unless it is severe or symptomatic (see earlier discussion).

OBSTETRICS: PREECLAMPSIA. Preeclampsia is a multisystem disease of pregnancy characterized by hypertension, proteinuria, and multiorgan involvement that may affect the kidneys, liver, pulmonary, and central nervous systems. In contrast to the usual volume-expanded status in pregnancy, patients with preeclampsia have reduced plasma volume, combined with endothelial dysfunction and hypoalbuminemia. Previously IV volume expansion was thought to be beneficial in treating hypertension in preeclampsia; however, this has not been borne out by later studies.[205,206] Furthermore, a clear association exists between positive fluid balance and the incidence of pulmonary edema in this condition.[207] Acute pulmonary edema occurs in between 5% and 30% of cases of preeclampsia. It is associated with increased hospital length of stay and is a leading cause of death in preeclamptic patients. Most cases present in the postpartum period, perhaps reflecting the autotransfusion into a vasoconstricted circulation that occurs after delivery. Low COP also contributes.

Patients with preeclampsia should receive restricted volumes of IV crystalloid (80 mL/h, including that received as drug diluents[208]), and fluid balance should be observed carefully. Oliguria should not be treated by administration of large volumes of fluids in the presence of normal renal function. This conservative strategy has not been associated with an increase in kidney injury.[209] Any blood loss in the peripartum or perioperative period should be replaced with an appropriate volume of crystalloid, colloid, or blood, depending on magnitude. Invasive monitoring should be used to direct fluid therapy in cases of severe preeclampsia.

Surgical Factors

NEUROSURGERY. Multiple physiologic factors mean that fluid and electrolyte therapy are a key component in the perioperative management of intracranial pathology. This management may be complicated by disturbances of water and Na^+ balance caused by neurosurgical diseases themselves. Much of the current fluid management in this area is based on knowledge of this physiology, experimental models, and gradual evolution of interventions investigated in small trials rather than large randomized studies.

The intact blood-brain barrier (BBB) excludes electrolytes and large molecules but allows passage of water. Extravascular brain water is therefore related to plasma osmolality, with cerebral edema a feature of hypoosmolar hyponatremic conditions. Intracranial diseases may compromise the integrity of the BBB, increasing the predisposition to edema. Cerebral perfusion also may be impaired if systemic blood pressure is inadequate in the face of increased intracranial pressure, particularly in pathologic conditions in which autoregulation is impaired. Rational management of fluids in neurosurgical patients should start with maintaining baseline blood volume and cerebral perfusion and avoiding significant decreases in serum Na^+, osmolality, and oncotic pressure. Several situations may require more specific management:

1. Increased intracranial pressure: Increasing serum osmolality may reduce total brain water and therefore intracranial pressure by creating brain-blood osmotic gradients. Mannitol and hypertonic saline given by bolus have been the pharmacologic mainstays in this area. The osmotic action of these drugs may be reduced if the BBB is disrupted by brain injury; however, they also have therapeutic benefits beyond simple osmotic effects.[210] A meta-analysis of the small studies available suggests that hypertonic saline may be superior to mannitol in reducing intracranial hypertension, but large-scale controlled studies are required to confirm this.[57] Conversely, using hypertonic saline in all patients with early traumatic brain injury without intracranial pressure monitoring has not been shown to improve outcomes.[58] Similarly, continuous infusion of hypertonic saline to induce persistent hypernatremia in the presence of cerebral edema also lacks evidence of benefit.[211] Restrictive fluid strategies have been advocated to minimize intracranial hypertension in severe traumatic brain injury. Although retrospective data analysis suggests that positive fluid balance is not associated with refractory intracranial hypertension, an association between hypervolemia and pulmonary edema was observed.[212]
2. Cerebral vasospasm: Manipulation of hemodynamics and hematocrit is traditionally used in the treatment of vasospasm after subarachnoid hemorrhage. This "triple-H" therapy (hypervolemia, hemodilution, hypertension) has entered practice based on small studies of efficacy rather than randomized trials.[213,214] Some workers, using extensive animal models, have advocated a hematocrit no lower than 30%, below which the benefits of reducing blood viscosity are outweighed by a reduction in O_2 delivery. They also caution against hypervolemia, both for its potentially injurious effects in the presence of a dysfunctional BBB and for the extracranial effects such as pulmonary edema.[215] "Prophylactic" hypervolemia aiming to prevent vasospasm is not recommended.[216]
3. An intracranial pathologic condition may itself be a cause of disturbances of both water and Na^+ balance through diabetes insipidus, cerebral salt wasting, or SIADH. This should be assessed and treated as described in the section on electrolyte imbalance.

Clear comparisons of crystalloid and colloid in a variety of neurosurgical settings are lacking. Of the available evidence, albumin is associated with an increase in mortality in traumatic brain injury compared with isotonic saline.[5] In the absence of more robust evidence, a mixture of isotonic crystalloids and colloids is advocated in other neurosurgical settings.[214,217]

TRAUMA. In patients with evidence of major traumatic hemorrhage, the key goals are to avoid clot disruption until definitive control of bleeding, to treat the acute coagulopathy of trauma, to maximize tissue O_2 delivery by the early use of packed red cell transfusion, and to avoid hypothermia and acidosis. This approach is termed hemostatic resuscitation. In the prehospital setting, restrictive fluid therapy may improve outcomes, particularly in penetrating trauma.[218] The approach should initially be one of permissive hypovolemia, with fluid administered to achieve cerebration rather than normotension in awake patients, systolic blood pressure of 70 to 80 mm Hg in penetrating trauma, or 90 mm Hg in blunt trauma.[219] The duration of organ hypoperfusion that may be involved with this approach should be minimized by rapid transfer for damage control intervention to stop bleeding, whether radiologic or surgical. Large volumes of IV crystalloids or colloids in early resuscitation will cause hemodilution and dilute clotting factors, and saline-based fluids may aggravate the acidosis associated with major blood loss. Rather, packed RBCs (PBRCs), clotting factors (e.g., fresh frozen plasma [FFP]) and platelets should be replaced early. Limited evidence, particularly from military populations and retrospective analyses, suggests "high" ratios of FFP to PRBC (e.g., 1:1-1:2) are associated with the best outcomes in massive transfusion compared with lower ratios (e.g., 1:9)[219,220]. Active warming should be used and clot stability improved with tranexamic acid.[221] Once hemostasis has been achieved, restoration of normal circulating volume and tissue perfusion is the goal, with ongoing blood, clotting factors, platelet, and fluid infusions targeting normalization of cardiac output and O_2 delivery, lactate levels, and blood clotting (best checked using near-patient whole-blood tests of clotting, such as thromboelastography). A small number of trials support the practice of GDT in the immediate perioperative trauma setting, but larger controlled trials are required. After surgery and initial resuscitation, much of the evidence for ongoing fluid approaches is derived from unselected critical care populations. As outlined previously, the evidence suggests that in established critical illness, aggressive GDT may be harmful.[218]

Patients with traumatic brain injury in addition to major hemorrhage present a dilemma because the raised cerebral perfusion pressure required for adequate cerebral blood flow in the face of raised intracranial pressure is at odds with the hypotensive resuscitation approach. In isolated head injuries, using fluids and vasopressors to achieve a mean arterial pressure *above* 90 mm Hg is recommended, with avoidance of hyponatremia and hypoosmolality to minimize cerebral edema.[210,217] Little evidence exists to inform resuscitation treatment in patients with mixed intracranial and extracranial trauma, so the strategy should be based on clinical judgment, prioritizing the requirements of the most severe injuries. Control of bleeding is particularly important to allow subsequent normalization of systemic blood pressure to meet the need for adequate cerebral perfusion. Even in general trauma, much of the evidence supporting current resuscitation approaches is derived from animal models and limited randomized trials, predominantly in young otherwise healthy subjects in the prehospital setting.[218] The needs of individual patients should therefore be taken into account, particularly because older patients with comorbidities may tolerate periods of hypoperfusion very poorly.

FREE TISSUE FLAP SURGERY. Free tissue flaps are frequently used during oncoplastic surgery, typically for breast reconstruction or after resection of head and neck tumors and involve the autologous transplantation of tissue to fill a defect, complete with arterial supply and venous drainage. Transplanted vessels are denervated and lack intrinsic sympathetic tone, but the feeding vessels are not; vasoconstriction in these feeding vessels related to cold and excessive doses of vasopressor must be avoided because it may threaten the perfusion of the flap. Flap blood flow depends on systemic blood pressure and blood viscosity, and hypervolemic hemodilution has traditionally been used to address these requirements. However, given the reduction in O_2 carrying capacity and potential for flap edema that this entails, a more conservative fluid strategy should be used, which may improve flap outcome.[219] The use of dextrans to improve blood flow is not currently favored, because no benefit has been demonstrated and the risks for medical complications is relatively high.[220] Free tissue flaps have disrupted lymphatics, which take several weeks to reconnect, making them particularly prone to interstitial edema. Large volumes of crystalloid—favoring increased capillary filtration—should be avoided and colloids used for blood volume expansion.[221]

INTRATHORACIC PROCEDURES. Any procedure within the thorax, including upper GI and thoracic surgery, can lead to postoperative respiratory problems, including ARDS and acute lung injury (ALI). The development of ARDS and ALI is partly due to the proinflammatory nature of one-lung ventilation,[222,223] modified by a host of other patient and surgical risk factors. In esophagogastrectomy, retrospective studies and case series have suggested reduced pulmonary complications with restrictive fluid strategies.[224-227] One retrospective observational study of esophagectomy patients found a cumulative fluid balance greater than 1900 mL from surgery to the second postoperative day to be an independent risk factor for other adverse outcomes, including death.[228] The use of diuretics to actively target fluid balance, degree of cardiovascular support, and presence or absence of epidurals was not explored in this study. More controlled trials of different fluid balance approaches are required in this population. However, the potential benefit of conservative fluid administration in this group is consistent with the large randomized study of patients with ARDS demonstrating improved pulmonary outcomes in those treated with a restrictive rather than liberal fluid regimen.[183] While maintaining adequate tissue perfusion, a cautious approach to fluid administration is recommended, both to minimize pulmonary complications and to avoid anastomotic edema.

HEPATIC RESECTION. Blood loss during liver parenchymal resection, a risk factor for worse outcomes, is associated with high venous pressure and backflow of blood through the valveless hepatic veins. One study has shown that a CVP of 5 cm H_2O or lower is associated with significantly lower blood loss and transfusion requirements.[229] Several techniques are used to maintain a low CVP, including conservative fluid management, at least until the hepatic resection is completed. Despite evidence that using a low CVP technique does not have adverse effects on renal or liver function,[230] a pragmatic compromise must be sought for each patient. Inducing hypovolemia during liver resection risks hemodynamic instability and end-organ hypoperfusion, increases the risk for air embolism, and reduces the physiologic reserve should massive blood loss occur. Once the liver resection is finished, a more generous fluid approach can be taken to ensure adequate circulating volume. This may be guided by invasive hemodynamic monitoring and minimally invasive cardiac output monitoring to provide a rational endpoint to fluid therapy in this phase.

MAJOR INTRAABDOMINAL SURGERY. Major intraabdominal operations, particularly those involving multiple organ resections for tumor, require careful perioperative fluid management. Major gynecologic operations such as pelvic exenteration or ovarian debulking and urologic procedures including cystectomy, radical nephrectomy, and major retroperitoneal lymph node dissection can involve dramatic fluid shifts in the perioperative period. Fluid losses during surgery are caused by prolonged peritoneal exposure, significant blood loss, and acute drainage of tumor-related ascites. The total volume lost is difficult to quantify, so cardiac output monitoring is valuable when combined with CVP and arterial pressure monitoring and serial blood gas analysis.[231,232] Intraoperative drainage of ascites is followed by fluid shift from the vascular space, as this reaccumulates postoperatively and may require large volumes to replace the ongoing loss. Another consequence of fluid redistribution is electrolyte abnormalities; hypokalemia and hypomagnesemia are frequently seen.

RENAL TRANSPLANT. The key goals of fluid therapy in the perioperative management of renal transplant are to ensure adequate renal perfusion to support early graft function and avoid fluid therapy side effects to which patients with impaired renal function may be susceptible. Traditionally, CVP-guided intraoperative fluid therapy has been advocated, using large volumes of crystalloid (up to 60-100 mL/kg) to achieve a CVP of 10 to 12 mm Hg or higher before reperfusion.[233] Recently, more conservative goals have been advocated, limiting crystalloid infusion to 15 mL/kg/h, aiming for a CVP of 7 to 9 mm Hg with no apparent increase in graft failure.[234] The role of alternative tools such as esophageal Doppler or pulse contour analysis to supplement or replace CVP-guided fluid therapy in this area also has been suggested, but so far only exploratory trials have been conducted.[235,236] Patients with renal failure may develop acidosis-related hyperkalemia when isotonic saline is infused during transplant,[44] so balanced crystalloid solutions, or even K$^+$-free, buffered dialysate solutions, should be used. The role of colloids in this population requires further study, although concerns over renal toxicity of starches may limit their use.[235] Postoperative fluid therapy should take into account the baseline maintenance requirements and the ongoing losses resulting from urine production.

LIVER TRANSPLANT. Liver transplantation involves a series of major physiologic disruptions that have direct relevance to fluid and electrolyte management.[237] Therapy should be guided by data from invasive monitoring, possibly including pulmonary artery catheterization. During phase I (preanhepatic), large volume blood loss and further fluid shifts resulting from drainage of ascites may occur. During phase II (anhepatic), a major reduction in venous return and therefore cardiac output may occur if a bicaval approach is used. Crystalloid and colloid infusion may be required along with vasopressors to maintain arterial pressure during this phase, although excessive volume administration risks right heart failure after unclamping. Absent citrate and lactate metabolism during this phase contributes to acidosis, hypocalcemia, and hypomagnesemia. On reperfusion and unclamping, cold, acidotic, hyperkalemic fluid is released into the circulation. Preparation for this must include normalizing pH and maintaining plasma K$^+$ in the low-normal range during phase II. This may require Ca$^+$, insulin-dextrose, hyperventilation, and even NaHCO$_3$ treatment. Phase III (reperfusion) leads to an acute rise in CVP, possibly with hepatic congestion and right heart strain. Systemic vasodilation and cardiac arrest may occur, leading to hypotension requiring vasopressor or inotrope support. If not given already, a bolus of CaCl$_2$ should be used to prevent hyperkalemia-related arrhythmias. Subsequent uptake of K$^+$ by a working graft may then require aggressive replacement. Ongoing infusion of fluids, red cells, and blood products should be guided by clinical blood loss. Other goals are to maintain a hematocrit of 26% to 32% and to correct the coagulopathy as guided by coagulation testing. There is increasing interest in the role of cardiac output-guided fluid in the perioperative care of patients undergoing liver transplantation.[238]

Perioperative Acid-Base Balance

PATRICK J. NELIGAN

KEY POINTS

- The presence of a significant acid-base abnormality often signals a sinister underlying problem.
- All acid-base abnormalities result from alterations in the dissociation of water.
- Only three factors independently affect acid-base balance—the arterial partial pressure of carbon dioxide (PaCO2), the strong ion difference (SID), and the total concentration of weak acids (A_{TOT}).
- Respiratory acidosis and alkalosis are caused by hypercarbia and hypocarbia, respectively.
- Metabolic acidosis is caused by decreased SID or increased A_{TOT}. Decreased SID results from accumulation of metabolic anions (shock, ketoacidosis, and renal failure), hyperchloremia, and free water excess. Increased A_{TOT} results from hyperphosphatemia.
- Metabolic alkalosis is caused by increased SID or decreased A_{TOT}. SID increases due to sodium gain, chloride loss, or free water deficit. A_{TOT} decreases in hypoalbuminemia and hypophosphatemia. This is particularly common in critical illness.
- Most acid-base disorders are treated by reversal of the cause.

Introduction—Why Is Acid-Base Balance Important?

Blood gas and pH analyses have been the most robust laboratory and bedside tools for identifying and monitoring critical illness since the advent of modern medicine. There is good reason to believe that understanding acid-base chemistry will continue to be important for physicians for decades to come.[1]

The human body is composed principally of water, partitioned into intracellular and extracellular compartments. The electrolyte composition of each of these spaces is tightly controlled to maintain homeostasis. Alterations in the relative concentrations of electrolytes and of carbon dioxide (CO_2) impact the tendency of water to auto-ionize into its component parts: hydrogen and hydroxyl ions.[2] Alterations in the water, gas, and electrolyte composition of the fluid compartments manifests as changes in the chemistry profile of body water and acid-base balance.

The hydrogen ion concentration is conventionally measured as pH (literally the "power of hydrogen"), the negative logarithmic value of its concentration. Deviations in extracellular pH away from the resting value of 7.4 have long been associated with acute and critical illness. Such deviations are known as "acid-base abnormalities."[3] All acid-base abnormalities result from changes in the local concentration of strong ions, weak acids, and CO_2.[2,4,5]

This chapter first looks at the basic science behind acid-base abnormalities. Subsequently, we explore the detection and treatment of acid-base conundrums, with specific reference to perioperative medicine and critical care.

What Are Acids and Bases?

The concept of acids and bases is relatively new in medicine,[6] and arose with the development of laboratory science in the early part of the 20th century. However, as early as 1831, O'Shaughnessy identified loss of "carbonate of soda" from the blood as a fundamental disturbance in patients dying of cholera.[7] This led directly to the development of crystalloid replacement therapy for hypovolemic shock. In 1909, L.J. Henderson coined the term "acid-base" balance.[8] He was able to define this process in terms of carbonic acid equilibrium. Henderson's work was later refined by Hasselbalch in 1916.[9] Their method described acid-base balance in terms of the hydration equation for CO_2[10]:

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$$

$$pH = pK_a + \log\ [HCO_3^-]/[H_2CO_3]$$

$$[\text{Total } CO_2] = [HCO_3^-] + [\text{Dissolved } CO_2] + [\text{Carbamino } CO_2] + [H_2CO_3]$$

$$\approx P_{CO_2} \times 0.03 \text{ mmol } CO_2/\text{L/mm Hg}$$

So, substituting into the foregoing equation:

$$pH = 6.1 + \log\ [HCO_3^-]/PCO_2 \times 0.03$$

This is the Henderson-Hasselbalch equation.

The introduction of this concept into clinical practice became possible with the development of volumetric CO_2 analysis by Van Slyke and others in 1919.[11] This led to

60 years of research and interest in CO_2 and its derivative, bicarbonate, as the principle agents that impact acid-base chemistry, despite the knowledge in the 1920s of the importance of chloride in acid-base equilibria.[12]

An understanding of acid-base chemistry in the human body requires familiarity with physical chemistry. Because the body contains a large quantity of water, the physical properties of water have enormous implication for maintenance of homeostasis. Water is a simple triatomic molecule. Its chemical formula is H_2O and its structural formula is H-O-H. The charge distribution of each covalent bond is unequal, and the molecule has a polar conformation and an H-O-H bond angle of 105 degrees. Water molecules attract and form hydrogen bonds with one another. Consequently, water has a high surface tension, a low vapor pressure, a high specific heat capacity, a high heat of vaporization, and a high boiling point.

Water molecules are in continual motion. Occasionally a collision generates sufficient energy to transfer a proton from one water molecule to another. Thus, water is always slightly dissociated into a negatively charged hydroxyl (OH^-) ion and a positively charged hydronium (H_3O^+) ion. Conventionally, this self-ionization of water is written as follows:

$$[H_2O] \leftrightarrow H^+ + OH^-$$

The symbol H^+ is convenient because, although protons dissociating from water have many aliases (such as H_3O^+ and $H_9O_4{}^+$), most physicians and chemists refer to them as hydrogen ions.

The self-ionization of water is miniscule. In pure water at 25°C, the $[H^+]$ and $[OH^-]$ are 1.0×10^{-7}mmol/L. The tendency for water to dissociate into its component parts is represented by the expression

$$K_{eq}H_2O = [H^+][OH^-]$$

The molarity of water is extremely high—55.5 M ("there is a lot of water in water"). As the concentration of water and the K_{eq} are constants, the ion-product dissociation constant (pKa) for water can be expressed as follows:

$$K_{eq}H_2O = K_{eq}(55.5) = K_w^{'} = [H^+][OH^-]$$

The implication is that the product of the concentrations of hydroxyl and hydrogen is constant, so when there is an increase in the concentration of hydrogen ions, there is a concomitant decrease in the concentration of hydroxyl ions, and vice versa.

Pure water is considered neutral because the relative concentrations of hydrogen and hydroxyl are equal at 1.0×10^{-7}mmol/L. A solution is considered *acidic* if the concentration of hydrogen ions exceeds that of hydroxyl ions ($[H^+] > 1.0 \times 10^{-7}$mmol/L, $[OH^-] < 1.0 \times 10^{-7}$ mmol/L). A solution is considered *alkaline* if the hydroxyl ion concentration exceeds the hydrogen ion concentration.

In 1903, Svante Arrhenius (1859-1927) established the foundations of acid-base chemistry. In an aqueous solution, an Arrhenius acid is any substance that delivers a hydrogen ion into the solution.[5] A base is any substance that delivers a hydroxyl ion into the solution. Because of its high dielectric constant, water is a highly ionizing solution. Therefore, substances with polar bonds will dissociate into their component parts (dissolve) in water. Brønsted and Lowry (BL) independently advanced this concept using slightly different terminology: an acid is a proton donor, a base a proton acceptor. Water itself is amphoteric and can act as either an acid or as a base. Thus, when hydrochloric acid (HCl) is dissolved in water, chloride, the acid, donates a proton to water, the base. Similarly, when potassium hydroxide (KOH) is dissolved in water, potassium, the base, receives a hydrogen ion from water, the acid or proton donor.

The degree of dissociation of substances in water determines whether they are strong acids or strong bases. Lactic acid, which has an ion pKa of 3.4, is completely dissociated at physiologic pH, and is a strong acid. Conversely, carbonic acid, which has a pKa of 6.4, is incompletely dissociated, and is a weak acid. Similarly, ions such as sodium (Na^+), potassium (K^+), and chloride (Cl^-), which do not easily bind other molecules, are considered *strong ions*—they exist free in solution. As each Na^+ delivers a hydroxyl moiety into extracellular fluid (ECF), it is functionally a base, as are all cations. As each Cl^- delivers a hydrogen moiety into ECF, it is functionally an acid, as are all anions. The hydrogen and hydroxyl ions delivered in this way bind to one another, forming water molecules, and relatively few free hydrogen or hydroxyl ions remain free in solution.

$$HCL + H_2O \rightarrow H_3O^+ + Cl^-$$

In this reaction, hydrogen chloride acts as a BL acid and water as a BL base.

$$NaOH + H_2O \rightarrow H_2O + OH^- + Na^+$$

In this reaction, water acts as a BL acid and sodium as a BL base.

$$OH^- + Na^+ + H_3O^+ + Cl^- = Na^+ + Cl^- + H_2O$$

Because of electrical neutrality, the hydrogen and hydroxyl ions delivered by chloride and sodium become water.

In summary, all acid-base reactions in the human body relate to the presence of charged particles within an aqueous environment. In the following section, how the components of ECF influence the acid-base status of the body, as measured by clinicians, is discussed. This is followed by an explanation of different acid-base abnormalities, and the tools used to identify them. These approaches are neither distinct from one another nor scientifically incompatible.

What Determines the Acidity or Alkalinity of a Solution?

Because all acid-base reactions are based on the principles of physical chemistry, three simple rules must be followed:[2]

1. *Electrical neutrality*: in aqueous solutions, in any compartment, the sum of all the positive charged ions must equal the sum of all the negative charged ions.

2. *Dissociation equilibria*: the dissociation equilibria of all incompletely dissociated substances, as derived from the law of mass action, must be satisfied at all times.
3. *Mass conservation*: the amount of a substance in a given compartment remains constant unless it is added, removed, generated, or destroyed. Therefore, the total concentration of an incompletely dissociated substance is the sum of concentrations of its dissociated and undissociated forms.

To determine the acid-base status of a fluid, all substances to which these rules could be applied must be accounted for. Fundamentally this involves counting up all the charges (and hence hydrogen and hydroxyl ions) delivered by strong cations (bases) and strong anions (acids), weak acid buffers, and CO_2.[13] A discussion of key groups follows.

STRONG IONS

The first group of ions, the strong ions, dissociate completely. The most abundant strong ions in the extracellular space are Na^+ and Cl^-. Other important strong ions include K^+, sulfate ($SO_4{}^{2-}$), magnesium (Mg^{2+}), and calcium (Ca^{2+}). These are occasionally referred to as "mineral" acids or bases because they cannot be metabolized.[6] Organic acids are generated from metabolism and accumulate when there is metabolic dysfunction—such as kidney failure, splanchnic hypoperfusion, or hormonal deficiency.

In a solution containing strong ions, created, for example, using specified concentrations of sodium hydroxide (NaOH) and HCL, the hydrogen ion concentration can be calculated by solving for electric neutrality:

$$(\mathrm{Na}^+ - \mathrm{Cl}^-) + (\mathrm{H}^+ - \mathrm{OH}^-) = 0$$

This creates two separate simultaneous equations[14]:

$$\mathrm{H}^+ = \sqrt{K'_W + \frac{([\mathrm{Na}^+] - [\mathrm{Cl}^-])^2}{4}} - \frac{([\mathrm{Na}]^+ - [\mathrm{Cl}^-])}{2}$$

and

$$\mathrm{OH}^- = \sqrt{K'_W + \frac{([\mathrm{Na}^+] - [\mathrm{Cl}^-])^2}{4}} + \frac{([\mathrm{Na}^+] - [\mathrm{Cl}^-])}{2}$$

These equations tell us that hydrogen and hydroxyl concentrations are determined by the Kw′ (water pKa), and the difference in charge between Na^+ and Cl^-. Because the former is constant, in this system ($[Na^+] - [Cl^-]$) must determine $[H^+]$ and $[OH^-]$. Given that the concentration of both Na+ and Cl^- are known, the net positive charge minus net negative charge can be quantified. It is the *strong ion difference* (SID).[14] Logically, in any solution, the sum total of the charges imparted by strong cations minus the charges from strong anions will represent the SID. SID independently influences hydrogen ion concentration (Fig. 48.1). In human ECF, SID is always positive.

$$\mathrm{SID} = \left([\mathrm{Na}^+] + [\mathrm{K}^+] + [\mathrm{Ca}^{2+}] + [\mathrm{Mg}^{2+}]\right) - ([\mathrm{Cl}^-] + [\mathrm{A}^-]) = 40 - 44\,\mathrm{mEq/L}$$

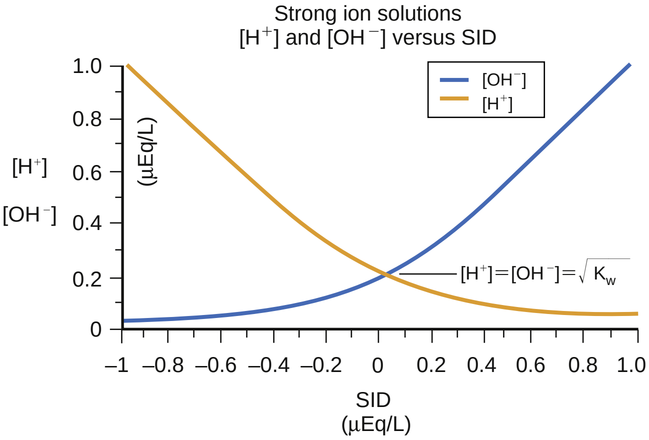

Fig. 48.1 Effect of Changes in the Strong Ion Difference (*SID*) on Hydrogen and Hydroxyl Ion Concentration. (Modified from Stewart PA. Modern quantitative acid-based chemistry. *Can J Physiol Pharmacol.* 1983;61:1444–1461.)

Hydroxyl ions almost always exceed hydrogen ions quantitatively in solution. The relationship between SID and $[H^+]$ is nonlinear in these conditions. Any change in SID will change both $[H^+]$ and $[OH^-]$ concentrations. Because of the Kw′, this relationship is inverse: as $[H^+]$ increases, $[OH^-]$ decreases (see Fig. 48.1). SID is an independent variable, and $[H^+]$ and $[OH^-]$ are dependent, meaning that the addition of hydrogen ions alone (without strong corresponding anions) cannot influence the pH of the solution.

WEAK ACID "BUFFER" SOLUTIONS

The degree of water dissociation, and thus the hydrogen ion concentration, is also influenced by charges derived from weak acids. These acids are partially dissociated compounds whose degree of dissociation is determined by the prevailing temperature and pH. The predominant molecules in this group are albumin and phosphate. Stewart used the term A_{TOT} to represent the total concentration of weak anions or acids that influence acid-base balance.[2]

The acid HA will only partly dissociate, represented by the equilibrium

$$[\mathrm{H}^+] \times [\mathrm{A}^-] = \mathrm{K}_\mathrm{A} \times [\mathrm{HA}]$$

K_A is the weak acid pKa. If we assume that HA and A^- play no further part in this reaction (the law of mass conservation), the amount of A^- present in the solution must equal the amount initially present, so:

$$[\mathrm{HA}] + [\mathrm{A}^-] = [\mathrm{A}_{\mathrm{TOT}}]$$

where $[A_{TOT}]$ is the total weak acid concentration.

In order to calculate the effect of weak acid dissociation on $[H^+]$, we must take into account water dissociation and electrical neutrality:

$$[\mathrm{H}^+] + [\mathrm{OH}^-] = \mathrm{K}'_\mathrm{w} \ (\text{water dissociation}).$$

$$[\mathrm{SID}] + [\mathrm{H}^+] - [\mathrm{A}^-] - [\mathrm{OH}^-] = 0 \ (\text{electrical neutrality}).$$

These four simultaneous equations determine the $[H^+]$ in this solution containing strong ions and weak acids. SID and A_{TOT} are independent variables. Kw′ and KA are constants. Consequently, the other variables [HA], $[H^+]$, $[OH^-]$, and $[A^-]$ must adjust to satisfy the foregoing equations. They are dependent variables.

CARBON DIOXIDE

Along with strong ions and weak bases, ECF contains CO_2. The concentration of CO_2 in ECF is determined by tissue production and alveolar ventilation. CO_2, when in solution, exists in four forms: CO_2 (denoted CO_2[d]), carbonic acid (H_2CO_3), bicarbonate ions ($HCO_3{}^-$), and carbonate ions $CO_3{}^{2-}$.

The concentration of CO_2(d) is determined by the solubility coefficient of CO_2 (SCO_2), which depends on body temperature, PCO_2, and other factors. Several equilibrium equations can be derived from the hydration of CO_2:

$$[CO_2\ (d)] = [Sco_2] \times Pco_2$$

The tendency for CO_2 to hydrate to H_2CO_3, and subsequently dissociate to H^+ and $HCO_3{}^-$, is reflected by the equation:

$$[CO_2\ (d)] \times [OH^-] = K_1 \times [HCO_3^-]$$

These equations can be combined together and with water equilibrium to the following:

$$[H^+] \times [HCO_3^-] = K_c \times pCO_2$$

$HCO_3{}^-$ also dissociates to release hydrogen ions and carbonate, the equilibrium reaction which is represented by this equation:

$$[H^+] \times [CO_3^{2-}] = K_3[HCO_3^-]$$

FACTORS INDEPENDENTLY INFLUENCING WATER DISSOCIATION

Now that we have looked at the different factors that may influence the concentration of hydrogen ions in a solution—strong ions, weak acids, and CO_2—we can combine the derived equations to a solve for $[H^+]$:

1. Water dissociation equilibrium:
$$[H^+] \times [OH^-] = K_W'$$
2. Weak acid dissociation equilibrium:
$$[H^+] \times [A^-] = K_A \times [HA]$$
3. Conservation of mass for weak acids:
$$[HA] + [A^-] = [A_{TOT}]$$
4. $HCO_3{}^-$ formation equilibrium:
$$[H^+] \times [HCO_3^-] = K_C \times pCO_2$$
5. Carbonate ion formation equilibrium:
$$[H^+] \times [CO_3^{2-}] = K_3 \times [HCO_3^-]$$
6. Electrical neutrality:
$$[SID] + [H^+] - [HCO_3^-] - [A^-] - [CO_3^{2-}] - [OH^-] = 0$$

There are six independent simultaneous equations, and just six unknown, dependent variables determined by them: [HA], $[A^-]$, $[HCO_3{}^-]$, $[CO_3{}^{2-}]$, $[OH^-]$, and $[H^+]$. There are three known independent variables: [SID], $[A_{TOT}]$, and PCO_2

Solving the equations for $[H^+]$:

$$[SID] + [H^+] - K_C \times P_C/[H^+] - K_A \times [A_{TOT}]/(K_A + [H^+]) - K_3 \times K_C P_C/[H^+]^2 - K_W'/[H^+] = 0$$

In other words, $[H^+]$ is a function of SID, A_{TOT}, PCO_2, and a number of constants. All other variables, most notably $[H^+]$, $[OH^-]$, and $[HCO_3{}^-]$ are dependent and cannot independently influence acid-base balance.

Acid-Base Abnormalities

The value of the physical chemistry ("Stewart") approach is that it allows us to use a simple model for understanding acid-base disturbances, as all abnormalities can be explained in terms of SID, A_{TOT}, or PCO_2.[2,14] Traditionally, acid-base disturbances have been classified as resulting from either alterations in arterial carbon dioxide ($PaCO_2$) tension (respiratory acidosis or alkalosis) or alterations in blood chemistry (metabolic acidosis or alkalosis).[16] This remains a useful classification, although it must be remembered that respiratory or metabolic abnormalities rarely occur independent of one another.

RESPIRATORY ACID-BASE ABNORMALITIES

Respiratory Alkalosis

The normal $PaCO_2$ is 40 mm Hg (5.3 kPa). Respiratory alkalosis occurs when there is an acute decrease in $PaCO_2$ as a result of hyperventilation. Acute respiratory alkalosis is characterized by a pH > 7.45, a low $PaCO_2$, and a low $HCO_3{}^-$. A simple rule of thumb for this reaction is as follows:

Acute respiratory alkalosis:

$$\Delta HCO_3^- = 0.2\ \Delta PaCO_2$$

The hyperventilating patient will present with symptoms and signs of vasoconstriction: lightheadedness, visual disturbances, dizziness, and hypocalcemia from increased binding of calcium to albumin. The hypocalcemia is caused by an increase in the available negative charge on albumin in alkaline states. Acute hypocalcemia is associated with paresthesia and tetany. In anesthesia practice, patients may hyperventilate preoperatively as a consequence of anxiety, and postoperatively secondary to pain, agitation, or a full bladder. More commonly, hyperventilation results from poor mechanical ventilation strategy and may result in significant systemic and, in particular, cerebral vasoconstriction. Therapeutic hyperventilation is no longer used to treat intracranial hypertension because of significant concerns regarding cerebral hypoperfusion and ischemia.

Respiratory Acidosis

Respiratory acidosis occurs when there is an acute rise in $PaCO_2$ usually associated with respiratory failure. This may result from problems with

- Central ventilator control—such as toxicity from anesthetic agents, benzodiazepines, or opioids, stroke, spinal cord injury;
- Peripheral ventilator control—such as myasthenia gravis, poliomyelitis, polymyopathy, or neuromuscular blockade;
- Ventilation-perfusion mismatch—associated with pneumothorax, pleural effusion, atelectasis, pneumonia, or pulmonary edema.

Clinically, patients have signs of CO_2 retention: cyanosis, vasodilatation, and narcosis.

Respiratory acidosis causes a rapid increase in $[H^+]$. Compensation for hypercarbia is slow, requiring increased urinary excretion of Cl^-,[8] and pH falls rapidly. A concomitant increase in the plasma HCO_3^- occurs and reflects a higher total CO_2 load. In the mid-1960s, Brackett, Cohen, and Schwartz elegantly described the relative changes in HCO_3^- in response to acute and chronic elevations in $PaCO_2$, providing us with extremely useful "rules of thumb":[17]

In acute hypercarbia, the bicarbonate concentration of plasma rises slowly

- An increase in $PaCO_2$ by 10 mm Hg (1.3 kPa) results in an increase in HCO_3^- by 1 mmol/L (1 mEq/L)

A patient returning to the intensive care unit from the operating room who has been under ventilation for several hours may be hypercapnic, for example, with a $PaCO_2$ of 80 mm Hg (10.5 kPa). Using this rule, the expected HCO_3 will be 28 mmol/L (Table 48.1).

In chronic respiratory failure, the total CO_2 load in the body increases substantially, reflected by relatively high levels of plasma HCO3⁻. There is a concomitant fall in plasma chloride, reflecting compensation for elevated levels of carbonic acid.

In chronic respiratory acidosis:

- $\Delta H^+ \text{ (nEq/L)} = 0.8\ (\Delta PCO_2)$
- An increase in $PaCO_2$ by 10 mm Hg (1.3 kPa) will increase plasma $[HCO_3^-]$ by 3 mmol/L (3 mEq/L)

A patient returning to the intensive care unit from the operating room, ventilated to a $PaCO_2$ of 40 mm Hg (5.3 kPa) but with high total CO_2, secondary to chronic respiratory failure (for example, from COPD), may fail to liberate from mechanical ventilation, due to acute metabolic alkalosis. Using the "rule" the patient's preoperative total CO_2 of 33 mEq/L (mmol/L) will indicate a baseline $PaCO_2$ of 70 mm Hg (9.3 kPa) for that patient (see Table 48.1).

For anesthesiologists, who routinely administer mechanical ventilation to patients with various levels of CO_2 retention, it is important to consider goals for both arterial and end tidal carbon dioxide ($etCO_2$) in the operating room. This should also include consideration of the impact of drugs, such as opioids and benzodiazepines, on respiratory function and on the effect of intravenous fluids on overall acid-base dynamics. For example, both isotonic saline (0.9%) solution and Ringer's Lactate (or Hartmann's) solution will cause progressive increase in extracellular chloride in a dose-dependent manner. This does not occur with truly balanced solutions such as Plasmalyte-148 or Normosol-R. In theory, this may impact postoperative CO_2-HCO_3^- homeostasis and respiratory function.

In critical illness, in particular in patients with acute respiratory distress syndrome (ARDS), there is general consensus among intensivists that aggressive mechanical ventilation to normalize pH and $PaCO_2$ is more harmful than "permissive" hypercapnia. Data support that such an approach—a "lung protective" strategy— is well tolerated,[18,19] and may indeed be beneficial.[20]

TABLE 48.1 Changes in Bicarbonate HCO_3^- and $PaCO_2$ in Acute and Chronic Hypercarbia

ACUTE HYPERCARBIA

Measured Bicarbonate	**Expected $PaCO_2$ in Acute Respiratory Failure**	
HCO_3^- mEq/L or mmol/L	**$PaCO_2$ mm Hg**	**$PaCO_2$ kPa**
24	40	5.3
25	50	6.6
26	60	8.0
27	70	9.3
28	80	10.5
29	90	11.8

CHRONIC HYPERCARBIA

Measured Bicarbonate	**Expected $PaCO_2$ in Chronic Respiratory Failure**	
HCO_3^- mEq/L or mmol/L	**$PaCO_2$ mm Hg**	**$PaCO_2$ kPa**
24	40	5.3
27	50	6.6
30	60	8.0
33	70	9.3
36	80	10.5
39	90	11.8
42	100	13

METABOLIC ACID-BASE DISTURBANCES

Metabolic acid-base disturbances are caused by abnormalities of extracellular water and electrolyte composition and serum protein levels. Using the terminology described above, metabolic acid-base abnormalities are caused by alterations in the SID or A_{TOT}, or both. An increase in the SID causes alkalemia; a decrease in the SID causes acidemia. The alternation may be caused by a change in the total or relative concentration of strong ions. For example, a decrease in the SID (i.e., more anions relative to cations)

TABLE 48.2 Classification of Primary Acid-Base Abnormalities

Abnormalities	Acidosis	Alkalosis
Respiratory	Increased PCO_2	Decreased PCO_2
Metabolic		
ABNORMAL SID		
Caused by water excess or deficit	Water excess = dilutional	Water deficit = contraction
	$\downarrow$ SID + $\downarrow$ $[Na^+]$	$\uparrow$ SID $\uparrow$ $[Na^+]$
Caused by electrolytes	Chloride excess	Chloride deficit
Chloride (measured)	$\downarrow$ SID $\uparrow$ $[Cl^-]$	$\uparrow$ SID + $\downarrow$ $[Cl^-]$
Other (unmeasured) anions, such as lactate and keto acids	$\downarrow$ SID $\uparrow$ $[UMA^-]$	—
ABNORMAL A_{TOT}		
Albumin [Alb]	$\uparrow$ [Alb] (rare)	$\downarrow$ [Alb]
Phosphate [Pi]	$\uparrow$ [Pi]	

[Alb], Concentration of serum albumin; *A_{TOT}*, to represent the total concentration of weak ions; *$[Cl^-]$*, concentration of chloride ions; *$[Na^+]$*, concentration of sodium ions; *PCO_2*, partial pressure of carbon dioxide; *[Pi]*, concentration of inorganic phosphate; *SID*, strong ion difference; *$[UMA^-]$*, unmeasured anions; ↑, increased; ↓, decreased.

(Modified from Fencl V, Jabor A, Kazda A, Figge J. Diagnosis of metabolic acid-base disturbances in critically ill patients. *Am J Respir Crit Care Med*. 2000;162:2246–2251.)

causes acidosis; this may occur because of a net increase in anions: mineral acids such as chloride or organic acids lactate or ketones (organic acids can be metabolized). In addition, SID can fall due to an increase in the volume of distribution of the same quantity of ions (Table 48.2). A useful rule of thumb is that for every 1 mEq/L fall in the SID, there is a 1 mEq/L fall in the $[HCO_3^-]$ from baseline (although the "normal" level varies with respiratory function; see Table 48.1)—and this approach is widely used to characterize metabolic acidosis. Likewise, for every 1 mEq/L increase in the SID, there is a 1 mEq/L increase in the $[HCO_3^-]$ from baseline—and this approach is widely used to characterize metabolic alkalosis. Note that, in all scenarios, $[HCO_3^-]$ is a *dependent* variable—dependent on changes in SID or A_{TOT}.

Metabolic acidosis is of clinical significance for two reasons: pathologies arising from the acidosis itself and pathologies arising from the cause of the acidosis. Acidosis is associated with alterations in transcellular ion pumps and increased ionized calcium. The result is vasodilation, diminished muscular performance (particularly myocardial), and arrhythmias. The oxyhemoglobin dissociation curve shifts rightward to increase oxygen offload into the tissues. Rapid-onset metabolic acidosis may be associated with profound hypotension, cardiac arrhythmias, and death. The malignancy of the acidosis is strongly related to the underlying disease process; lactic acidosis caused by circulatory shock is more malevolent than hyperchloremic acidosis.[13] The body is hyperresponsive to acidosis. Increasing hydrogen ion content in cerebrospinal fluid activates the respiratory center to stimulate respiration. Alveolar ventilation increases, reducing arterial CO_2 content, hence reducing the total body $[H^+]$. Bicarbonate concentration simultaneously falls, due to buffering activity, and due to the reduction in total CO_2. As a result, the blood pH falls less in metabolic acidosis compared with respiratory acidosis.

Metabolic alkalosis rarely occurs as a result of acute illness. Symptoms and signs of metabolic alkalosis include widespread vasoconstriction, lightheadedness, tetany, and paresthesia. The main compensatory mechanism is hypoventilation that may delay weaning from mechanical ventilation in critically ill patients.

In normal ECF, the SID is 40 to 44 mEq/L, this positive charge being balanced principally by weak acids (without which the pH of blood would be 11.9). Anything that increases the SID will increase the relative concentration of cations to anions and alkalinize the solution. Anything that decreases the SID will decrease the relative concentration of cations to anions and will acidify the solution. Hence, if the extracellular compartment volume is expanded with free water (no electrolytes), the components of the system are diluted, with relatively more dilution of more abundant moieties (sodium rather than chloride); the result is a reduction in SID and "dilutional acidosis." This is rarely seen in clinical practice, due to the renal water clearance. Conversely, if free water is removed from the ECF, for example from increased evaporative losses, there is an increase in the relative concentration of charged moieties, and this concentration effects more abundant ions and compounds (sodium rather than chloride). The SID increases and the patient develops a "contraction alkalosis" (see Table 48.2). This is commonly seen in clinical practice, in particular following the administration of loop diuretics that have a greater impact on water removal over salt.

In hospital medicine, "normal saline" (NaCl 0.9%—NS), containing 154 mEq (3.5 g) of sodium and 154 mEq (5.5 g) of chloride, is commonly used. The SID of this solution is 0. As each liter of fluid delivers relatively more chloride than sodium (as the baseline proportions in ECF are 1.4:1—SID 40), progressive hyperchloremia results. This reduces SID and results in "hyperchloremic acidosis."[21]

Any process that removes chloride without sodium, such as vomiting or aggressive nasogastric suctioning with a loss of HCl, causes metabolic alkalosis (hypochloremic alkalosis) due to an increase in SID. The alkalosis is caused by chloride loss, which obeys the law of conservation of mass (i.e., there is a finite quantity available in the ECF), not hydrogen ions, whose source—water—is unlimited. Severe diarrhea, which is associated with loss of both potassium and sodium, reduces the SID, and is associated with metabolic acidosis. Aggressive use of diuretics causes a net loss of free water over sodium and chloride and causes contraction alkalosis.

The most significant form of metabolic acidosis is associated with a net gain of "unmeasured" (organic—that is electrolytes not conventionally measured on serum chemistry analysis) anions and, consequently, a decreased SID.

1. In dysoxia, liver dysfunction, and, in particular, states of severe stress, lactate is produced, reducing the SID and causing acidosis
2. In out-of-control diabetes (ketoacidosis) or during starvation or liver disease, β-hydroxybutyrate and acetoacetate are produced, reducing SID and causing acidosis
3. In severe renal failure, Cl^-, SO_4^{2-}, PO_4^{3-} ("fixed renal acids"), and various other metabolic intermediaries are not excreted, causing acidosis.

The total weak acid pool, principally serum albumin and phosphate, is also an important determinant of acid-base status. Hyperphosphatemia has long been associated with the acidosis of renal failure. Hypoalbuminemia is common in critical care. Hypoalbuminemia decreases A_{TOT} and is associated with metabolic alkalosis.[22,23] There is a strong association between hypoalbuminemia and severity of critical illness. Albumin deficits result from four different homeostatic changes: reprioritization of hepatic protein production favoring production of acute phase reactants and limiting albumin synthesis; capillary leak with loss of albumin into the interstitium; breakdown of pre-existing albumin so that its constituent amino acids can be used for protein synthesis; and replacement of plasma with protein-free fluids.

The impact of hypoalbuminemia on acid-base balance has been grossly underestimated. Stewart's original theory has been subsequently modified by Fencl and Figge.[24] The serum albumin concentration is the core negative charge offsetting the net positive charge of the SID.[22] Consequently, the presence of hypoalbuminemia may mask the detection of acidosis[25] caused, for example, by unmeasured anions (UMA), when using conventional tools of acid-base chemistry: pH, bicarbonate, base deficit, and the anion gap (AG).[26] Indeed, the presence of hypoalbuminemia has significant implications, not least for its association with adverse outcomes.[27] Hyperalbuminemia is very unusual; in cholera, when associated with hemoconcentration, it results in acidosis.[28]

Regulation of Acid-Base Balance

Extracellular hydrogen ion concentration appears to be tightly controlled by the body. In all probability this regulation reflects a need to prevent rapid changes in extracellular electrochemical balance from interfering with the function of transcellular ion pumps. To prevent fluctuation a variety of intracellular and extracellular buffering systems have evolved. A *buffer* is a solution of two or more chemicals that minimizes changes in pH in response to the addition of an acid or base. Ideally, a buffer has a pK_a that is equal to the pH, and an ideal body buffer has a pK_a between 6.8 and 7.2. Most biologically salient buffers are weak acids.

It is valuable to view control of hydrogen ion concentration in terms of volatile and metabolic acids (mineral and organic). The major source of acid in the body is the volatile acid CO_2, which produces 12,500 mEq of H^+ a day, mostly excreted by the lungs. In contrast, only 20 to 70 mEq of hydrogen ion-promoting anions are excreted daily thru the kidney. Volatile acid is principally buffered by hemoglobin (Hb). Deoxygenated Hb is a strong base and there would be a huge rise in the pH of venous blood if Hb did not bind the hydrogen ions produced in oxidative metabolism.

Carbon dioxide easily passes through cell membranes. Within the erythrocyte CO_2 combines with H_2O, under the influence of the enzyme carbonic anhydrase, to form H_2CO_3, which ionizes to hydrogen and bicarbonate. Hydrogen ions bind to histidine residues on deoxyhemoglobin (the "Haldane" effect), and bicarbonate is actively pumped out of the cell. Chloride moves inward to maintain electroneutrality (the chloride shift) and to ensure the continued production of carbonic acid. CO_2 is also buffered directly by Hb (carbaminohemoglobin) and by plasma proteins (carbamino proteins). Venous blood contains 1.68 mmol/L extra CO_2 over arterial blood: 65% as HCO_3^- and H^+ bound to Hb, 27% as carbaminohemoglobin (CO_2 bound to Hb), and 8% dissolved.

When respiratory failure occurs, the principal CO_2 buffering system, Hb, becomes overwhelmed, leading to the rapid development of acidosis. In response, the kidney excretes an increased chloride load, using NH_4^+, a weak cation, for electrochemical balance. Thus ECF osmolality is maintained. This process is conventionally referred to as "metabolic compensation." Chronic respiratory acidosis is associated with increase in total body CO_2 content, reflected principally by an increase in serum bicarbonate (see Table 48.1). Hypercapnia is associated with a progressive increase in CSF bicarbonate, reflecting an overall increase in total CO_2 load. Compensation for this hypercarbia is a reduction in CSF chloride[29] and an increase in CSF SID.[30-32] This is probably controlled by active transport mechanisms across the blood-brain barrier or at the level of the choroid plexus and can be blocked by furosemide and acetazolamide.[33-36] The result is a rightward shift in the PCO_2 response curve: the respiratory center responds to hypercarbia by increasing respiratory drive at a higher PCO_2 level than under normal conditions.

Bicarbonate is a dependent variable that increases or decreases with PCO_2.[37] The rate of conversion of CO_2 to HCO_3^- is dependent on carbonic anhydrase activity and occurs slowly. Thus, it is possible to mathematically determine whether a rise in $PaCO_2$ is acute or longstanding (see Table 48.1). Metabolic acid is buffered principally by increased alveolar ventilation, producing respiratory alkalosis, and extracellular weak acids. These weak acids include plasma proteins, phosphate, and bicarbonate. The bicarbonate buffering system (92% of plasma buffering and 13% overall) is probably the most important extracellular buffer. The pK_a of bicarbonate is relatively low (6.1), but the system derives its importance from the enormous quantity of CO_2 present in the body. The coupling of bicarbonate and H_2O produces CO_2, which is then excreted through the lungs, increasing alveolar ventilation. Physicians must be aware of the importance of this compensatory mechanism. For example, anesthetized or critically ill patients on controlled mechanical ventilation lose the capacity to regulate their own PCO_2. Consequently, the combination of acute metabolic and respiratory acidosis can cause a devastating reduction in pH.

The major effect of the kidney on acid-base balance relates to renal handling of sodium and chloride ions. As dietary intake of sodium and chloride is roughly equal, the kidney excretes a net chloride load, using NH_4^+, a weak cation, to electrochemically neutralize urinary chloride.[38]

In metabolic acidosis, the kidneys preferentially excrete chloride. In metabolic alkalosis, chloride is retained and sodium and potassium are excreted. The presence of bicarbonate in the urine reflects the need to maintain electrical neutrality. Abnormalities in the renal handling of chloride may be responsible for several inherited acid-base disturbances. In renal tubular acidosis, there is inability to excrete Cl^- in proportion to Na^+.[39] The diagnosis can be made by observing a hyperchloremic metabolic acidosis, with inappropriately low levels of Cl^- in the urine: the urinary SID is positive. If the urinary SID is negative, the process is not of renal origin. Similarly, pseudohypoaldosteronism appears to be due to high reabsorption of chloride.[40] Bartter syndrome is caused by a mutation in the gene encoding the chloride channel—CLCNKB—that regulates the Na-K-2Cl cotransporter (NKCC2).[41]

The other causes of hyperchloremic metabolic acidosis are gastrointestinal losses (diarrhea, small bowel or pancreatic drainage), parenteral nutrition, excessive administration of saline, and the use of carbonic anhydrase inhibitors.

Analytic Tools Used in Acid-Base Chemistry

Acid-base balance is a core component of the clinical evaluation of the acutely and critically ill. Arterial blood gas (ABG) analysis provides immediate information on the status of the patient's respiratory system and whether or not a state of acidosis or alkalosis is present. By applying a variety of empiric rules, the information contained in an ABG is often sufficient to allow one to identify the presence, cause, and progression of a disease. The diagnostic sensitivity of blood gas analysis is augmented when a blood chemistry panel, glucose and lactate, and blood and urinary ketones measurements are added.

Several different approaches to acid-base balance are in widespread use.[42] These can be described as descriptive, based on changes in the Henderson Hasselbalch equation; semi-quantitative, based on calculations and nomograms; or quantitative, based on physical chemistry. These may be used interchangeably—and I would suggest that there is no best or worst approach, merely different methods of analyzing the data. The descriptive approach utilizes the inter-relationship between $PaCO_2$ and $[HCO_3^-]$ to detect and diagnose acid-base abnormalities. An extension of this is the anion gap (AG). The semi-quantitative approach includes the buffer base (BB) concept, the standardized base excess (BE), and the base-deficit gap (BDG). The quantitative approach utilizes SID and A_{TOT} and is quantified using the strong ion gap (SIG).

Over time, quantitative analyses are likely to dominate the clinical approach to acid-base chemistry. Many of the early approaches were developed at a time when only total CO_2 levels could be measured. Indeed, the continued popularity of the AG is curious given that serum lactate and blood ketones can now be easily measured at the bedside.

THE DESCRIPTIVE (CO_2-BICARBONATE [BOSTON]) APPROACH

Schwartz, Brackett, Relman, and colleagues at Tufts University in Boston developed the most popular descriptive approach to acid-base chemistry in the 1960s. Their formulation uses acid-base maps and the mathematical relationship between CO_2 tension and plasma bicarbonate (or total CO_2), derived from the Henderson-Hasselbalch equation, to classify acid-base disturbances in term of two independent variables: $PaCO_2$ and $[HCO_3^-]$.[43,44] To validate this approach, a number of patients with known acid-base disturbances, at steady states of compensation, were evaluated. The degree of compensation, relative to what was considered normal, was measured for each disease state. The investigators were able to describe six primary states of acid-base imbalance, using linear equations or maps, relating hydrogen ion concentration to PCO_2 for respiratory disturbances, and PCO_2 to HCO_3^- concentration for metabolic disturbances (Fig. 48.2). For any given acid-base disturbance, an expected HCO_3^- concentration was determined. These were then compiled into a series of mathematical rules (see Table 48.1 and Box 48.1). For most simple disturbances, this is a reasonable approach. As discussed above, in acute respiratory acidosis, the $[HCO_3^-]$ will increase by 1 mmol/L (mEq/L) for every 10 mm Hg (1.3 kPa) elevation in $PaCO_2$ above 40 mm Hg (5.3 kPa). In chronic respiratory acidosis, the $[HCO_3^-]$ will increase by 3 mEq/L for every 10 mm Hg (1.3 kPa) elevation in $PaCO_2$ above 40 mm Hg (5.3 kPa).

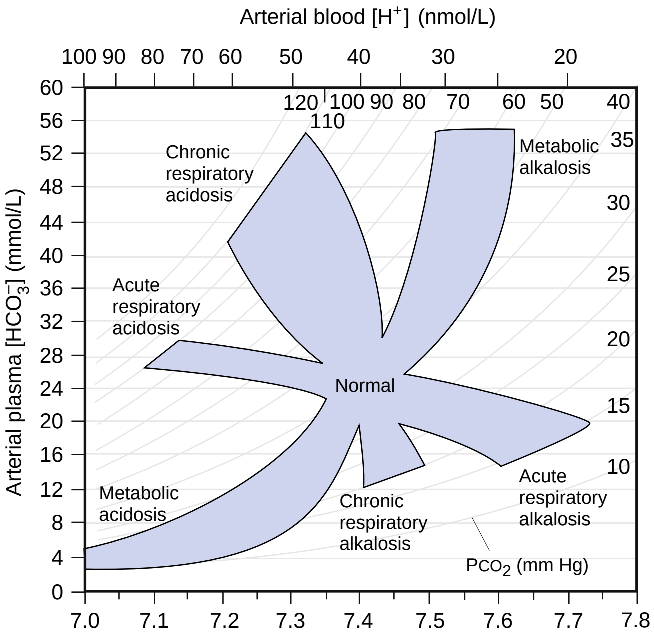

Fig. 48.2 Acid-Base Nomogram Using the Boston Approach. Different acid-base disturbances can be distinguished based on the relative values of PCO_2 and HCO_3^-. (Modified from Brenner BM, Rector FC. *The Kidney*. 3rd ed. Philadelphia, PA: WB Saunders; 1986:473.)

In acute metabolic acidosis, the $[HCO_3^-]$ falls by 1 mEq/L for every 1 mEq/L in strong anions. The respiratory center is activated, resulting in a predictable fall in the $PaCO_2$. This was neatly characterized by Winters in a pediatric population in 1967 and remains robust.[45] In acute metabolic acidosis, the $PaCO_2$ (in mm Hg) falls predictably, using the $1.5 \times [HCO_3^-]$ plus 8 rule. For example, if the $[HCO_3^-]$ is 12 mmol/L (mEq/L), then the expected $PaCO_2$ is $1.5 \times 12 + 8 = 26$ mm Hg. If the $PaCO_2$ is higher than this, then compensation is inadequate and there is a concomitant respiratory problem (for example, ketoacidosis in the presence of a respiratory tract infection). Winters also described expected compensation using the BE approach (see next section): for every 1 mEq/L reduction in the BE the $PaCO_2$ is expected to fall by 1 mm Hg—otherwise "compensation" is inadequate.

BOX 48.1 The Descriptive (CO_2–HCO_3^-) Approach to Acid-Base

Respiratory Disorders

Acute Respiratory Acidosis

$$\text{Expected } [HCO_3^-] = 24 + [(\text{measured } PaCO_2 - 40)/10]$$

Chronic Respiratory Acidosis

$$\text{Expected } [HCO_3^-] = 24 + 4\,[(\text{measured } PaCO_2 - 40)/10]$$

Acute Respiratory Alkalosis

$$\text{Expected } [HCO_3^-] = 24 - 2\;[(40 - \text{measured } PaCO_2)/10]$$

Chronic Respiratory Alkalosis

$$\text{Expected } [HCO_3^-] = 24 - 5\;[(40 - \text{measured } PaCO_2)/10]\;\;(\text{range: } \pm 2)$$

Metabolic Disorders

Metabolic Acidosis

$$\text{Expected } PaCO_2 = 1.5 \times [HCO_3^-] + 8\;(\text{range}: \pm 2)$$

Metabolic Alkalosis

$$\text{Expected } PaCO_2 = 0.7\;[HCO_3^-] + 20\;(\text{range}: \pm 5)$$

In metabolic alkalosis, in order to restore pH to homeostatic levels, it is necessary to retain carbonic acid, and hypoventilation occurs, ultimately resulting in increased $[HCO_3^-]$. The expected $PaCO_2$ equals $0.7 \times [HCO_3^-] + 20$ (in mm Hg). So if a patient has a $[HCO_3^-]$ of 34 mEq/L (mmol/L), then the $PaCO_2$ should be 44 mm Hg.

Using these maps, equations, and rules, physicians can determine the nature of most respiratory and metabolic acid-base disturbances and in a manner that is usually accurate. Although there is a mathematical relationship in place, alterations in $[H^+]$ and $[HCO_3^-]$ do not reflect cause and effect. For example, chronic hypoventilation is associated with an increase in PCO_2 and $[HCO_3^-]$. Many physicians have incorrectly assigned the increase in $[HCO_3^-]$ as compensation for raised PCO_2. It is not. The increased HCO_3^- concentration reflects increased total CO_2 in the body.

Although the PCO_2-HCO_3^- approach is relatively accurate for most disturbances, and is particularly useful for respiratory problems, there are several inherent pitfalls, particularly in relation to the metabolic component. First, the approach is not as simple as it seems, requiring the clinician to refer to confusing maps or to learn formulas and perform mental arithmetic. Second, the system neither explains nor accounts for many of the complex acid-base abnormalities seen in perioperative and critically ill patients, such as those with acute acidosis in the setting of hypoalbuminemia, free water deficit or excess, hyperchloremia, hyperphosphatemia, or concurrent metabolic acidosis and alkalosis.

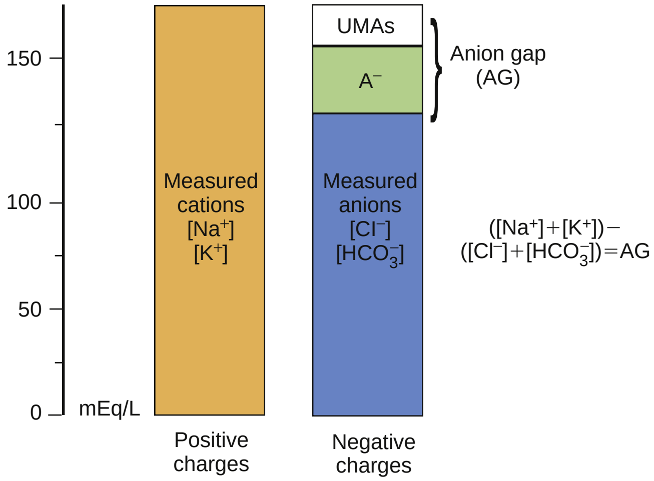

Fig. 48.3 The Anion Gap Represents the Difference in Charge Between Measured Cations and Measured Anions. The missing negative charge is made up of weak acids *(A^-)*, such as albumin and phosphate, and strong unmeasured anions *(UMAs)*, such as lactate.

ANION GAP APPROACH

The most widely used tool for investigating metabolic acidosis is the AG, developed by Emmett and Narins in 1977.[46] It is based on the law of electrical neutrality. It is entirely consistent with the physical chemistry approach, described in the next section, and is usually used alongside the Boston approach to acid-base. Again, the system is based on data that were not easily available or known at the time of publication: the contribution to electrical neutrality ascribed to weak acids (phosphate and albumin) and UMA. The sum of the difference in charge of the common extracellular ions reveals an unaccounted for "gap" of −10 to −12 mEq/L. There are three widely used variants of the AG (Fig. 48.3), depending on whether or not potassium and lactate are included:

$$\text{Anion gap (simple)} = ([Na^+] - [Cl^-] + [HCO_3^-]) = 12 \text{ to } 14 \text{ mEq/L}$$

$$\text{Anion gap (conventional)} = ([Na^+] + [K^+] - ([CL^-] + [HCO_3^-])) = 14 \text{ to } 18 \text{ mEq/L}$$

$$\text{Anion gap (modern)} = ([Na^+] + [K^+] - ([Cl^-] + [HCO_3^-] + [\text{lactate}^-])) = 14 \text{ to } 18 \text{ mEq/L}$$

If the patient develops a metabolic acidosis, and the gap widens to, for example, >20 mEq/L, then the acidosis is caused by UMA (usually renal acids or ketones). If the gap does not widen, then the anions are being measured, and the acidosis has been caused by hyperchloremia (bicarbonate cannot independently influence acid-base status) or lactate (if used). While this is a useful tool, it is weakened by the assumption of what is or is not a "normal gap."[47] The AG frequently underestimates the extent of the metabolic disturbance.[26] The majority of critically ill patients are hypoalbuminemic, and many are also hypophosphatemic. Consequently, the gap may be normal in the presence of UMA. This has been extensively studied by Fencl and Figge, who have provided us with a variant known as the "corrected AG":[26]

$$\text{Anion gap corrected (for albumin)} = \text{calculated anion gap} + 0.25\left(\text{normal albumin}^* - \text{observed albumin g/L}\right).$$

*which may vary between populations/labs; if g/dL used the factor is 2.5.

In this corrected form the AG accurately quantifies metabolic acidosis, and it is useful in discriminating an acidosis due to UMA from one reflecting hyperchloremia, in a previously healthy patient (e.g., in acute trauma). Moviat and colleagues have demonstrated that the AG corrected for albumin accurately detects complex acid-base abnormalities in intensive care.[48]

Another version of the AG is the delta AG (delta ratio DR—Box 48.2), an approach that has successfully predicted adverse outcomes in critical illness.[49] Simply, if the AG is normal, or unchanged, and the bicarbonate level falls, then the delta ratio will be less than 0.4, and a hyperchloremic acidosis is present. A DR between 1 and 2 is what one would expect from metabolic acidosis due to UMA or lactate. If the ratio is greater than 2, mixed acid-base abnormalities are present. Although on the surface, this process is relatively simple, it assumes that the clinician knows the normal AG and bicarbonate for that particular patient. In addition, it does not result in a clear diagnosis other than hyperchloremia.

BOX 48.2 **The Delta Anion Gap (Delta Ratio)**

$$\begin{aligned}\text{Delta ratio} &= \Delta\text{Anion gap}/\Delta\,[\text{HCO}_3^-]\ \text{or}\ \uparrow\text{anion gap}/\downarrow[\text{HCO}_3^-]\\ &= \frac{\text{Measured anion gap} - \text{Normal anion gap}}{\text{Normal}\ [\text{HCO}_3^-]\ -\ \text{Measured}\ [\text{HCO}_3^-]}\\ &= \frac{(\text{AG} - 12)}{(24 - [\text{HCO}_3^-])}\end{aligned}$$

Fig. 48.4 is a decision tree that uses this descriptive approach to acid-base.

THE SEMI-QUANTITATIVE (BASE DEFICIT/ EXCESS [COPENHAGEN]) APPROACH

In metabolic acidosis, the addition of UMA to the ECF results in a net gain of one hydrogen ion for each anion. This is buffered, principally by bicarbonate, such that each anion gained results in an equivalent fall in the bicarbonate concentration. Thus, the change in the bicarbonate concentration from baseline should reflect the total quantity of net

Delta ratio

Delta ratio	Clinical assessment
<0.4	Hyperchloremic normal AG acidosis
<1	High AG and normal AG acidosis
1 to 2	Pure anion gap acidosis Lactic acidosis: average value 1.6 DKA more likely to have a ratio closer to 1 because of urine ketone loss
>2	High AG acidosis and concurrent metabolic alkalosis or preexisting compensated respiratory acidosis

Fig. 48.4 The Descriptive ("Boston") Approach to Acid-Base Balance. *DKA*, Diabetic ketoacidosis; *AG*, Anion gap.

anions gained. Adherents to the descriptive approach to acid-base refer to this as the “delta” bicarbonate. However, this is problematic, as it does not separate out the effect of CO_2 metabolism on the $[HCO_3^-]$.

In 1948, Singer and Hastings[50] proposed that changes in the whole blood BB could be used to quantify the metabolic component independent of Henderson-Hasselbalch. The BB represented the sum of the bicarbonate and the nonvolatile buffer ions (essentially the serum albumin, phosphate, and Hb). Applying the law of electrical neutrality, the BB was forced to equal the electrical charge difference between strong (fully dissociated) ions. Thus, normally $BB = [Na^+] + [K^+] - [Cl^-]$. Alterations in BB represented changes in strong ion concentrations (which could not be easily measured in 1948). BB increases in the presence of a metabolic alkalosis and decreases in metabolic acidosis. The major drawback of BB measurements is the potential for changes in buffering capacity associated with alterations in Hb concentration and pH.

Following the development of sophisticated electrodes for measuring CO_2 tension in Copenhagen in the early 1950s,[51] Astrup and Jorgensen developed the standard bicarbonate—the bicarbonate concentration at 37°C and at a $PaCO_2$ of 40 mm Hg (5.3 kPa).[52] Building upon this work, Siggaard-Anderson and Astrup[53] recognized that PCO_2 and $[HCO_3^-]$ were not independent variables. As a result, they derived the BE as a measure that could differentiate respiratory from metabolic acid-base disturbances. As defined, the BE is the amount of strong acid (strong anion) or base (strong cation) required to return the pH to 7.4, assuming that PCO_2 is constant at 40 mm Hg (5.3 kPa) and that the temperature is 37°C.[54] Like the Boston group, the Siggaard-Anderson data were derived from observations on a large population of patients. The investigators carefully titrated known amounts of acid or base to blood maintained by tonometry at various $PaCO_2$ values and a wide range of hemoglobin concentration at 37°C. These studies led to the development of an alignment nomogram (Fig. 48.5 and Table 48.3) that allowed for the determination of BE from a single measurement of pH, $PaCO_2$, and Hb concentration at 37°C. Current algorithms for computing the BE are derived from the Van Slyke equation (1977).[55]

$$BE = (HCO_3^- - 24.4 + [2.3 \times Hb + 7.7] \times [pH - 7.4] \times (1 - 0.023 \times Hb))$$

The most commonly used estimation of BE uses just the bicarbonate and pH by the following equation:

$$BE = 0.93 \times ([HCO_3^-] - 24.4 + 14.83 \times [pH - 7.4])$$

There is a very high level of agreement between this calculation and the empirical data that were used to construct the original nomogram. The calculation is accurate in vitro, but not in vivo because of the dynamic buffering activity of Hb within the acid-base paradigm of gas and electrolyte exchange. Moreover, weak acids such as phosphate and albumin also contribute to nonbicarbonate buffering. Hence the following formula is now used to calculate the standard base excess (SBE) or the BE of ECF:

$$SBE = ((HCO_3^- \text{ actual mEq/L}) - 24.8 + (16.2 \times (pH - 7.40))$$

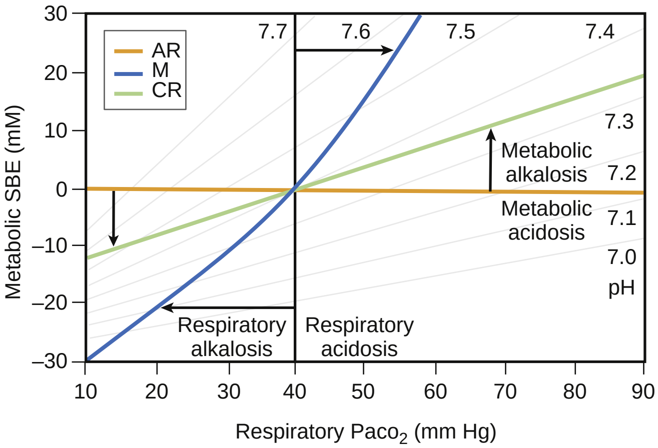

Fig. 48.5 Acid-Base Nomogram Using the Copenhagen Approach as Revised by Schlichtig. The various acid-base disturbances can be distinguished based on PCO_2 and base deficit or excess, here referred to as standard base excess *(SBE)*. *Arrows* represent changes as the body compensates for acute acidosis or alkalosis. *AR*, Acute respiratory acidosis or alkalosis; *CR*, chronic respiratory acidosis or alkalosis; *M*, metabolic acidosis or alkalosis. (From Schlichtig R, Grogono AW, Severinghaus JW. Human $Paco_2$ and standard base excess compensation for acid-base imbalance. *Crit Care Med*. 1998;26:1173–1179.)

TABLE 48.3 Changes in Standard Base Deficit or Excess in Response to Acute and Chronic Acid-Base Disturbances

Disturbance	SBDE vs. $PaCO_2$
Acute respiratory acidosis	$\Delta BDE = 0$
Acute respiratory alkalosis	$\Delta BDE = 0$
Chronic respiratory acidosis	$\Delta BDE = 0.4\ \Delta PaCO_2$
Metabolic acidosis	$\Delta PaCO_2 = \Delta BDE$
Metabolic alkalosis	$\Delta PaCO_2 = 0.6\ \Delta BDE$

Δ, Change in value; *BDE*, base deficit or excess; *$PaCO_2$*, partial pressure of arterial carbon dioxide.

Modified from Narins RB, Emmett M. Simple and mixed acid-base disorders: a practical approach. *Medicine (Baltimore)*. 1980;59:161–187.

The value of 16.2 mEq/L approximates all of the nonbicarbonate buffers in ECF (albumin, phosphate, and mean ECF Hb). It is likely that Siggaard-Andersen overestimated the impact of Hb as an extracellular buffer and underestimated the uptake and release of chloride into erythrocytes in the peripheries and lungs respectively.[56]

Although various descriptions of this approach to acid-base chemistry refer to the *BE*—and that term is reported on blood gas forms, when a negative base excess (1-BE) is reported—the correct terminology refers to it as the *base deficit*.[57] For simplicity, in the following discussion, I will refer to the BE, keeping in mind that it may be positive (metabolic alkalosis) or negative (metabolic acidosis).

Application of simple mathematical rules allows for use of the BE in each of the common acid-base disturbances (Box 48.3 and Fig. 48.6). For example, in acute respiratory acidosis or alkalosis, BE does not change. Conversely, in acute metabolic acidosis, the magnitude of change of the $PaCO_2$ (in millimeters of mercury) is the same as that of the BE (in mmol/L or mEq/L).

BOX 48.3 Calculation of the Base Excess Gap[12,58,59]

$$\mathrm{BE_{NaW}}\ \text{(water and sodium effect)} = 0.3\ ([\mathrm{Na^+}_{\ meas}]\ \text{-140})\ \mathrm{mEq/L}$$

$$\mathrm{BE_{Cl}}\ \text{(chloride effect)} = 102 - [\mathrm{Cl^-}\ \text{effective}]\ \ (\mathrm{mEq/L})$$

$$\mathrm{BE_{Pi}}\ \text{(phosphate effect)} = (0.309 \times (\mathrm{pH} - 0.47)) \times \mathrm{Pi\ mEq/}$$

$$\mathrm{BE_{prot}}\ \text{(protein effect)} = (42 - [\text{Albumin g/L}])\ *\ \ (0.148 \times \mathrm{pH} - 0.818)$$

$$\mathrm{BE_{calc}} = \mathrm{NE_{NaW}} + \mathrm{BE_{Cl}} + \mathrm{BE_{PO4}} + \mathrm{BE_{prot}}$$

$$\mathrm{BE_{Gap}} = \mathrm{BE_{calc}} - \mathrm{BE_{actual}} - [\text{lactate mEq/L}]$$

A Simplified Calculation of the Base Excess Gap[60]

$$\mathrm{BE_{NaCl}} = ([\mathrm{Na^+}] - [\mathrm{Cl^-}]) - 38$$

$$\mathrm{BE_{Alb}} = 0.25\ \ (42 - \text{albumin g/L})$$

$$\mathrm{BE_{NaCl}} - \mathrm{BE_{Alb}} = \mathrm{BDE_{calc}}$$

$$\mathrm{BE_{actual}} - \mathrm{BE_{calc}} - [\text{lactate}] = \text{BEG} = \text{the effect of unmeasured anions or cations}$$

*This approach involves calculating the base deficit excess for sodium, chloride, and free water ($\mathrm{BE_{NaCl}}$), and that for albumin ($\mathrm{BE_{Alb}}$). The result is the calculated BE ($\mathrm{BE_{calc}}$). This is subtracted from the measured BE to find the BE gap.

There has been considerable discussion over the past 60 years about the merits and demerits of the BE, as compared to the $\mathrm{CO_2}$-$\mathrm{HCO_3}^-$ system. In reality, there is little difference between the two; both equations and nomograms were derived from patient data and abstracted backward. Calculations use bicarbonate as measured on a blood gas analyzer. Consequently, for most patients, either approach is relatively accurate but may be misleading because they do not allow the clinician to distinguish between, for example, acidosis due to lactate or chloride, or alkalosis due to dehydration or hypoalbuminemia. These measures may miss the presence of an acid-base disturbance entirely; for example, a hypoalbuminemic (metabolic alkalosis) critically ill patient with a lactic acidosis (metabolic acidosis) may have a normal range pH, bicarbonate, and BE. This lack of precision may lead to inappropriate or inadequate therapy.

Changes in the BE occur secondary to alterations in the relative concentrations of sodium, chloride, free water, albumin, phosphate, and UMA. By calculating the contribution of the individual components of the BE it is possible to identify: (1) contraction alkalosis, (2) hypoalbuminemic alkalosis, (3) hyperchloremic acidosis, (4) dilution acidosis (if indeed it exists), and (5) acidosis secondary to UMA. This approach, which can be labelled the base-deficit gap, has been proposed by Gilfix and Magder (see Box 48.3)[58] and simplified subsequently by Balasubramanyan and associates[59] and Story and associates.[60] The BDG should mirror the SIG (below) the corrected AG.

The simplified calculation as proposed by Story et al. is very easy to calculate at the bedside and in the majority of situations (see Box 48.3) replicates the more complex calculations originally proposed by Gilfix and Magder.[58]

STEWART APPROACH

A more accurate reflection of true acid-base status can be derived using the Stewart or physical chemical approach, subsequently updated by Fencl.[5,15] This approach is based on the concept of electrical neutrality, a small advance from the AG. There exists, in plasma, a SIDa $\left[\left(\mathrm{Na^+} + \mathrm{Mg^{2+}} + \mathrm{Ca^{2+}} = \mathrm{K^+}\right) - \left(\mathrm{Cl^-} + \mathrm{A^-}\right)\right]$ of 40 to 44 mEq/L, balanced by the negative charge on bicarbonate and $\mathrm{A_{TOT}}$ (the BB—SIDe). There is a small difference between SIDa (apparent SID) and BB (SIDe—effective SID) that represents a SIG and quantifies the amount of UMA present (Fig. 48.7).

$$\text{SIDa (apparent SID)} = \left([\mathrm{Na^+}] + [\mathrm{K^+}] + \left[\mathrm{Mg^{2+}}\right] + \left[\mathrm{Ca^{2+}}\right]\right) - [\mathrm{Cl^-}]$$

$$\text{SIDe (effective)} = [\mathrm{HCO_3^-}] + [\text{charge on albumin}] + [\text{charge on Pi}]\ (\text{in mmol/L})$$

Weak acids' degree of ionization is pH dependent, so one must calculate for this:

$$[\mathrm{alb^-}] = [\text{alb g/L}] \times (0.123 \times \mathrm{pH} - 0.631)$$

$$\text{Pi (mmol/L)} = [\mathrm{PO_4}] \times (0.309 \times \mathrm{pH} - 0.469)$$

$$\text{Strong Ion Gap (SIG)} = \text{SIDa} - \text{SIDe}$$

Unfortunately, the SIG may not represent unmeasured strong anions but only all anions that are unmeasured. For example, if a patient has been resuscitated with gelatin, his/her SIG will increase. Further, SID changes quantitatively in absolute and relative terms when there are changes in plasma water concentration. Fencl has addressed this by correcting the chloride concentration for free water ($\mathrm{Cl^-}$*corr*) using the following equation[5]:

$$[\mathrm{Cl^-}]\,corr = [\mathrm{Cl^-}]\,\text{observed} \times ([\mathrm{Na^+}]\text{normal} / [\mathrm{Na^+}]\text{observed}).$$

This corrected chloride concentration may then be inserted into the SIDa equation above. Similarly, the derived value for UMA can also be corrected for free water by substituting UMA for $\mathrm{Cl^-}$ in the above equation.[25] In a series of nine normal subjects, Fencl estimated the "normal" SIG as 8 ± 2 mEq/L.[25]

Calculation of SIG is cumbersome. The data required are more extensive and thus more expensive than other approaches and there is much confusion about the normal range of SIG. It is unclear, in standard clinical practice, that SIG has any advantage over AGc (which is SIG without calcium, magnesium, and phosphate—which usually cancel out each other's charges).

In all likelihood no single number will ever allow us to make sense of complex acid-base disturbances. Fencl[25] has suggested that, rather than focusing on AG or BDE, physicians should address each blood gas in terms of all alkalinizing and acidifying effects: respiratory acidosis/alkalosis, the presence or absence of abnormal SID (due to

water excess/deficit, measured electrolytes, or unmeasured electrolytes), and abnormal A_{TOT}. Consider the following patient, described by Fencl[25](data in mEq/L unless otherwise stated):

Na 117, Cl 92, Ca 3.0, Albumin 6.0 g/L
K 3.9, Mg 1.4, Pi 0.6 mmol/L

ABG: pH 7.33, PCO_2 30 mm Hg, HCO3 15

Derived values would be:

AG 13, $AG_{corrected}$ 23, BE −10, SID 18, $Cl_{corrected}$ 112, $UMA_{corrected}$ 18.

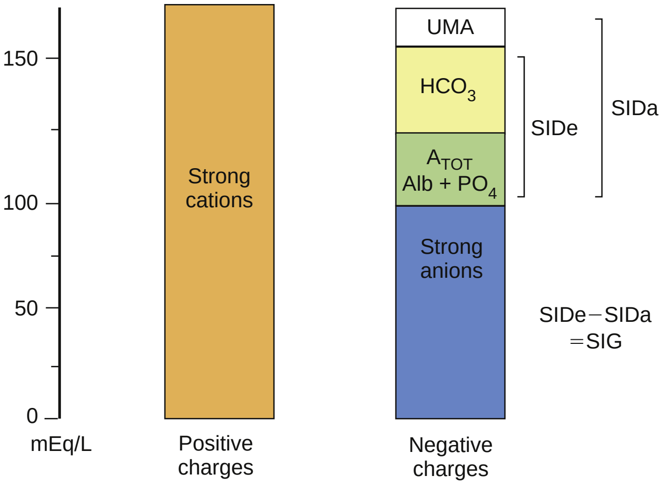

Fig. 48.7 The Strong Ion Gap: SID Apparent is the Sum of ATOT plus [HCO_3^-]. SID effective is the real SID. The difference between the two is made up of unmeasured anions (*UMA*). *SID*, Strong ion difference; *SIG*, strong ion gap.

Using traditional methodology, one would describe this as a nongap metabolic acidosis and look for causes of bicarbonate wasting such as renal tubular acidosis or gastrointestinal losses. The degree of respiratory alkalosis is appropriate for the degree of acidosis ($\Delta BD = \Delta PCO_2$). However, the Fencl-Stewart approach reveals a much more complex situation. SID is reduced to 18 mEq/L, caused by free water excess, UMA, and, surprisingly, hyperchloremia (see the corrected chloride). However, the degree of acidosis does not mirror the metabolic disturbance because of the alkalizing force of hypoalbuminemia. The corrected AG mirrors the change in SID, but this alteration is grossly underestimated by the base deficit. This patient has a dilutional acidosis, a hyperchloremic acidosis, and a lactic acidosis!

In conclusion, for the majority of patients presenting to the emergency room or operating suite who have been previously healthy, the use of tools such as the base deficit or AG to assess metabolic disturbances remains reasonable, particularly if corrected for albumin. However, for critically ill patients, the most effective method of interpreting acid-base conundrums involves unraveling simultaneous acidifying and alkalinizing processes and using calculations to distinguish between the various forces at play. Unfortunately, a clinician's ability to interpret such information is dependent on the amount of available data. A simple blood gas alone may camouflage a significant acid-base disturbance.

In the next section, we will look at the causes of many commonly seen acid-base disturbances in different clinical settings.

Acid-Base Problems in Perioperative and Critical Care Medicine

RESPIRATORY ACIDOSIS AND ALKALOSIS

In perioperative medicine respiratory acid-base abnormalities are an uncommon complication of prolonged spontaneous breathing under anesthesia, inadequate mechanical ventilation (both acute respiratory acidosis) or excessive mechanical ventilation (respiratory alkalosis) (Table 48.4). Acute respiratory acidosis results from hypoventilation or increased dead space ventilation. Patients may manifest respiratory distress characterized by respiratory acidosis in the recovery room PACU or surgical ICU. Assessment begins with an examination of the patient's breathing pattern (Fig. 48.8): slow shallow breathing indicates impaired respiratory drive, rapid shallow breathing suggests chest wall or lung pathology, and obstructed breathing signifies airway obstruction. Blood gas analysis of acute respiratory acidosis will reflect a dramatic fall in pH, an elevated $PaCO_2$, and a slight rise in HCO_3^- (by 1 mEq/L [mmol/L] for every 10 mm Hg [or 1.2 kPa] rise in $PaCO_2$). The BE should be zero. Respiratory acidosis as a complication of anesthesia is relatively common—excessive sedation (particularly opioids), partial neuromuscular blockade, intraoperative hypoventilation, pneumothorax, etc. It may also complicate CO_2 insufflation during laparoscopy—the patients' minute ventilation should be dynamically adjusted intraoperatively to maintain $etCO_2$ levels near baseline.

TABLE 48.4 Acid-Base Disturbances Commonly Seen Perioperatively

Disorder	Cause
Respiratory acidosis	Hypoventilation; narcosis, incomplete reversal of neuromuscular blockade
Respiratory alkalosis	Hyperventilation; anxiety, pain
Metabolic acidosis due to unmeasured anions (widened gap acidosis)	Hypoperfusion—lactic acidosis; diabetic ketoacidosis; renal failure
Metabolic acidosis due to measured anions (non-gap hyperchloremic acidosis)	Hyperchloremia—“normal” saline and saline-containing fluids; renal tubular acidosis; bladder reconstructions
Metabolic acidosis due to free water excess (hyponatremia, dilution acidosis)	Hypotonic fluid administration; sodium loss—diarrhea; administration of hyperosmolar fluids—mannitol, alcohol, hyperproteinemia
Metabolic alkalosis	Hyperventilation of patient with history of CO_2 retention (COPD); sodium gain (sodium bicarbonate, massive blood transfusion); chloride loss—nasogastric suctioning

For patients with COPD (or other causes of chronic respiratory failure), it is worthwhile, preoperatively, to calculate the baseline $PaCO_2$ on a patient from the total CO_2 on blood chemistry panel. As discussed earlier, the total CO_2 (HCO_3^-) rises by 3 mEq/L (mmol/L) for every 10 mm Hg (1.3 kPa) rise in $PaCO_2$. A patient, for example, with a baseline total CO_2 of 33 mEq/L (mmol/L) would be expected to have a baseline $PaCO_2$ of 70 mm Hg (9.3 kPa). For intraoperative management, the $etCO_2$ should be maintained, if the patient is undergoing mechanical ventilation, between 3 and 5 mm Hg (0.5 –1 kPa) of baseline (the $PaCO_2$-$etCO_2$ gradient increases with age and nonsupine positioning).

If the patient is hypoventilating, perioperatively, the pH falls, the $PaCO_2$ rises, but the rise in the total CO_2 (HCO_3^-) is lower than expected. If this patient's $PaCO_2$, postoperatively, is 90 mm Hg (12 kPa) and the total CO_2 (HCO_3^-) is

Fig. 48.8 Using the Breathing Pattern to Determine the Cause of Acute Respiratory Distress and Respiratory Acidosis.

35 mmol/L (mEq/L), then the patient has acute or chronic respiratory acidosis. This problem may be compounded by the patient's lack of pulmonary reserve and the negative impact on the respiratory center by opioids and other anesthetic agents. Consideration should be given to administration of noninvasive ventilation to restore $PaCO_2$ to what is normal for that patient.

In emergency medicine and critical illness, respiratory acidosis complicates a wide variety of pathologies. Most commonly, these cause a problem of the patient "can't breathe"—a neuromuscular or anatomical problem—or the patient "won't breathe"—a central nervous system pathology. The latter includes neurologic injury (stroke, spinal cord injury, botulism, tetanus, and toxic suppression of the respiratory center [opioids, barbiturates, benzodiazepines]). Patients "can't breathe" due to a variety neuromuscular disorders (Guillain-Barré syndrome, myasthenia gravis), flail chest, hydro-hemo-pneumo-thorax, pulmonary edema, and pneumonia. Failure to ventilate, as manifest by respiratory acidosis, may result from abdominal hypertension and abdominal compartment syndrome, where diaphragmatic excursion is impeded by high intra-abdominal pressures, often with associated oliguria and hypotension.

Acute respiratory alkalosis is caused by hyperventilation, either due to anxiety or pain, central respiratory stimulation (as occurs early in salicylate poisoning), or excessive artificial ventilation. In acute respiratory alkalosis the pH is above 7.45, the $PaCO_2$ below 40 mm Hg (5.3 kPa), and the $[HCO_3^-]$ falls by 2 mEq/L (mmol/L) for every 10 mm Hg (1.3 kPa) fall in $PaCO_2$. There is no change in the BE. So, if a patient has a $PaCO_2$ of 30 mm Hg, the $[HCO_3^-]$ should be 22 mEq/L (mmol/L).

Acute respiratory alkalosis usually accompanies acute metabolic acidosis, in which case the reduction in PCO_2 from baseline (usually 40 mm Hg) is equal to the magnitude of the base deficit (see Table 48.3). The fall in bicarbonate, from baseline, is significantly greater than that seen in primary respiratory alkalosis, due to the consumption of bicarbonate as extracellular buffer (the $[HCO_3^-]$ falls 1 mEq/L for every 1 mEq/L gain in strong anions). For example, in a patient with a lactic acidosis whose lactate is 10 mEq/L, the BE should be −10, the $[HCO_3^-]$ 10 mEq/L (mmol/L) lower than baseline, and the PCO_2 30 mm Hg. If the PCO_2 is higher than expected, then there is a concomitant problem with the respiratory apparatus. An example would be a multi-trauma patient, where massive blood loss leads to lactic acidosis and a flail chest causes respiratory acidosis.

Metabolic Acidosis and Alkalosis

METABOLIC ACIDOSIS

Acute metabolic acidosis is caused by an alteration in SID or A_{TOT}. SID is changed by an alteration in the relative quantity of strong anions to strong cations. Anions, mineral or organic, can be gained, as occurs with lactic-, renal-, keto-, and hyperchloremic acidosis, or cation can be lost, as occurs with severe diarrhea or renal tubular acidosis.

Acute metabolic acidosis is characterized by a pH of < 7.35 and a fall in both $PaCO_2$ and (HCO_3^-) below the patient's baseline. For patients without COPD or chronic CO_2 retention, this represents a $PaCO_2$ < 40 mm Hg (5.3 kPa) and a $[HCO_3^-]$ below 24 mEq/L (mmol/L), there is a negative BE (base deficit) whose magnitude represents the net strong anion gain. This simple approach indicates that an acidosis is present, and that it is metabolic in origin. To further investigate the acidosis, one or more of the analytical tools described above may be employed. The most widely used tool is the AG, which should be adjusted for albumin. This differentiates hyperchloremic acidosis from acidosis caused by other measured and UMA. In the setting of metabolic acidosis, where possible, these anions should be directly measured—lactate, ketones, phosphate, albumin or surrogate markers of anion accumulation—serum creatinine and the osmolar gap. Causes of metabolic acidosis that are commonly encountered by anesthesiologists are discussed below.

LACTIC ACIDOSIS

The presence of lactic acidosis is an excellent marker of acute critical illness, the magnitude of which often reflects the degree of hyperlactatemia. Lactic acidosis occurs when the production of lactate in the body is greater than the liver's capacity to clear it—there is a problem of overproduction or inadequate clearance.

Lactic acid is produced physiologically as a degradation product of glucose metabolism. In nature it exists as two isoforms: L-lactate which is produced by the human body and is measured by blood gas analyzers, and D-lactate which can only be produced by fermentation by bacteria. The formation of L-lactate (lactate) from pyruvate is catalyzed by lactate dehydrogenase. Lactate is used as a "buffer" in isotonic fluids, principally lactated Ringer's solution and Hartmann's solution; these contain a racemic mixture of both D and L lactate at a concentration of 14 mmol/L each.

Under normal conditions, the ratio of lactate to pyruvate ratio is less than 20:1. In anaerobic conditions, for example following vigorous exercise, lactate levels increase dramatically, and high levels of circulating lactate are frequently interpreted as evidence of increased glycolytic activity. However, lactate is often produced under aerobic conditions. Activation of β-adrenergic receptors in skeletal muscle by stress (increased circulating catecholamines) or exogenous infusion (epinephrine/norepinephrine infusions) increases [lactate], resulting in aerobic glycolysis. Lactate is metabolized to pyruvate and then into glucose (gluconeogenesis) in the liver and subsequently to CO_2 and H_2O (the Cori cycle). Hence the lactate in Ringer's lactate (or Hartmann's) solution is considered to be a source of bicarbonate. This is only the case if the liver is capable of handling the lactate load.

Plasma lactate and arterial pH should be measured early in any critically ill patient—it is now a diagnostic component of the definition of septic shock.[61] A lactate concentration > 2 mEq/L (mmol/L) is clinically significant and a level of 5 mEq/L(mmol/L) in the presence of metabolic acidosis is severe.[62] Isolated hyperlactatemia in the absence of acidosis is of unclear clinical significance.[63]

Traditionally, lactic acidosis has been described as taking one of two forms: type 1 (may also be termed type A, global inadequate oxygen delivery) is seen in hypovolemic/hemorrhagic shock while type 2 (type B) occurs despite normal global oxygen delivery and tissue perfusion. Lactic acidosis may also develop in situations where there is significant regional hypoperfusion. Examples include bowel ischemia, where lactate is produced in large quantity due to glycolysis despite global oxygen delivery that is normal. Type 2 lactic acidosis is associated with any state in which circulating catecholamines (endogenous or exogenous) are in excess. Examples include simple exercise and the hyperinflammatory state of trauma or sepsis. Type 2 lactic acidosis may also be seen in cyanide poisoning (associated with sodium nitroprusside), with biguanides (metformin, which blocks hepatic gluconeogenesis), and in hypercatabolic diseases such as lymphoma, leukemia, AIDS, or diabetic ketoacidosis (DKA). In critical illness, type 1 and type 2 lactic acidosis frequently coexist.

It is universally accepted that lactic acidosis is a sensitive marker of disease severity.[64] Persistence of lactic acidosis strongly predicts poor outcomes in acute illness.[65-67] Rapid clearance (i.e., reduced plasma concentration presumably due to reduced production and increased metabolism) of lactate has been associated with improved outcomes.[68,69] It remains controversial whether it is possible to institute therapy that improves outcomes and simultaneously increases lactate clearance. Simplistically, improved overall perfusion consequent of blood or isotonic fluid administration should reduce glycolysis and reduce lactate production, increasing hepatic blood flow and increasing metabolism. However, not all patients who are under-resuscitated are hyperlactatemic, and probably the minority of patients who are hyperlactatemic are under-resuscitated. Although fluid resuscitation with the goal of normalizing serum lactate may be associated with improved outcomes, excessive or late fluid resuscitation increases mortality.[70] It is important to note that, following fluid bolus, plasma lactate rapidly falls, perhaps due to hemodilution, and then falls slowly, at 10% to 20% per hour, due to rate-limited hepatic clearance. If plasma lactate does not fall, fluid resuscitation should be discontinued.[71]

The presence of evidence of good overall oxygen delivery and normal consumption, as measured by cardiac output monitors and mixed venous oxygen saturation, in lactic acidosis is not reassuring. Indeed, bowel ischemia may be indicated by otherwise unexplained lactic acidosis, and the availability heuristic associated with sepsis may result in delayed diagnosis and inappropriate fluid resuscitation (Fig. 48.9).

Metformin is associated with severe lactic acidosis, a phenomenon that appears more likely when the patient has liver dysfunction, is dehydrated, is in heart failure, has suffered acute kidney injury (AKI), or is septic.[72] The mechanism of harm is unknown, although metformin is thought to impair oxidative metabolism in hepatocyte mitochondria, and block gluconeogenesis. Renal impairment appears to be a significant risk factor. The patient presenting with metformin-associated lactic acidosis frequently looks reasonably well, despite serum lactate that may exceed 10 mmol/L. There is no specific treatment except for withdrawal of the drug, gentle rehydration, and patience.

D-lactate-induced acidosis can occur, typically in patients with short bowel syndrome and bacterial overgrowth. It manifests as a widened AG acidosis where no other potential source of metabolic acid is identified. Crucially, point-of-care blood gas analyzers do not measure D-lactate. However, many laboratories are able to measure the molecule, and this test should be considered in a high-risk patient (post major abdominal surgery) with unexplained acidosis.

A Clinical Approach to Lactic Acidosis

Ketoacidosis

Ketone bodies—acetone (<2%), acetoacetate (20%), and 3-β-hydroxybutyrate (βOHB) (78%)—are normal by-products of fat metabolism. They are produced when fatty acids are metabolized by the liver, when glucose is unavailable as an energy source. During ketogenesis, acetoacetate is generated from acetyl co-enzyme A. This either enters mitochondria to be converted to βOHB or it spontaneously decarboxylates to acetone. Ketones are transported by blood to the tissues, in particular the brain, where they are used as energy sources. Under normal dietary conditions, ketones are undetectable in blood and urine. However, in situations where fat becomes the primary source of energy (for example in starvation or low-carbohydrate diets), ketones can be measured in blood (principally βOHB) and urine (principally acetoacetate). In a variety of clinical situations, such as prolonged starvation, alcoholism, alcoholic- or obesity-related steatohepatitis, and, most commonly, insulin deficiency (diabetes mellitus), a dramatic increase in circulating ketones occurs. As these are strong anionic compounds, ketones reduce SID, resulting in metabolic acidosis. When this occurs in type-1 diabetes (T1D), it is known as diabetic ketoacidosis (DKA).

DKA may be the first manifestation of T1D, or may result from poor glycemic control or specific stress triggers, such as infection, trauma, or surgery. Typically there is an imbalance between the relative quantity of insulin and glucose-promoting hormones (cortisol, epinephrine, and glucagon). Blood glucose increases, exceeding the renal reabsorption threshold. This results in glycosuria, osmotic diuresis, dehydration, and the vicious cycle of activation of stress hormones. This leads to increased metabolism of fatty acids and, in the absence of insulin, or consequent of severe insulin resistance, there is unrestrained oxidation of fatty acids to ketones in the liver. Regardless of the cause, there is usually elevated blood glucose, significant dehydration, and depletion of potassium, phosphorous, and magnesium.

The diagnosis of DKA is relatively simple. Usually there is a clear history of either diabetes or polyuria and polydipsia: the patient presents to the emergency room with hyperglycemia and glycosuria, and, usually, positive urinary ketones. Ketoacidosis is confirmed by performing ABG analysis. Every hospital has a protocol for the management of DKA. Insulin is administered by an infusion (with or without an initial bolus). This may be a weight-based fixed-rate infusion (0.1 units of insulin per kilo per hour) or more traditional infusion based on blood glucose.[73] The patient is resuscitated with several liters of isotonic crystalloid (usually isotonic saline [0.9%] solution), and when blood glucose falls within a "controlled" range, intravenous dextrose is administered. Insulin suppresses ketone production. Glucose is required to assist ketone metabolism, which can take some time. Two major mistakes are made in the management of DKA. Administration of 0.9% NaCl results in an entirely predictable hyperchloremic acidosis; this may or may not be harmful but may be perceived incorrectly as persistence of ketoacidosis. A small study that compared NS with Plasmalyte-148 (a balanced salt solution [BSS]) reported that patients receiving the balanced solution instead of NS had more rapid resolution of metabolic acidosis, less hyperchloremia, improved blood pressure profile, and greater urinary output.[74]

The second error is very important for anesthesiologists. As noted above, the majority of ketones in the body are in the form of βOHB. These can only be identified by measuring "blood" ketones. Urinary ketone sticks measure only acetoacetate.[75] The absence of ketones in the urine does not eliminate the diagnosis of ketoacidosis (particularly if it is not associated with diabetes). Blood ketones are easily measured using handheld devices (although these may be hard to find in hospitals due to the current disenfranchisement of point-of-care testing). Interestingly, as βOHB must be metabolized to acetoacetate, urinary ketones may actually increase during the time that the whole body ketone load is falling and ketosis is resolving.

Patients presenting for emergency surgery may have multiple simultaneous acid-base abnormalities, and physicians often miss ketoacidosis due to availability bias—the presence of elevated lactate may result in search satisficing—and a major metabolic abnormality is missed.[76] Despite fluid resuscitation and source control, the acidosis may not resolve. This in turn may lead to inappropriate therapy such as renal replacement therapy (RRT) and sodium bicarbonate administration, neither of which are of any value in ketoacidosis. All forms of ketoacidosis require insulin therapy and, eventually, glucose administration. Ketoacidosis of non-diabetic origin may take many hours, and occasionally days, to resolve.

Renal Acidosis

The kidney excretes water and a variety of metabolic byproducts, principally derived from proteins. The kidney also excretes surplus electrolytes, some of which are strong ions, including chloride, sulfate, formate, urate citric acid cycle metabolites (fumarate, citrate), and phosphate. These accumulate in AKI and cause "renal acidosis." Early in AKI, hyperchloremia is the principle source of acidosis; subsequently, 50% to 60% of acidosis is caused by UMA and up to 30% is associated with hyperphosphatemia.[77] Fifty percent of patients with AKI in critical illness have a normal AG.[77]

AKI, in perioperative medicine, may accompany hypotension, hypovolemia, renal hypoperfusion (from aortic cross clamping or intraabdominal hypertension), rhabdomyolysis, sepsis, or urinary obstruction. Irrespective of the cause, patients develop oliguria, volume overload, and hyperkalemia secondary to metabolic acidosis.

The identification of metabolic acidosis in AKI is key to the diagnosis, severity, and therapeutic strategy in AKI. Although serum creatinine is the most widely used marker of renal function, isolated readings are unhelpful. Fluid resuscitation can artificially lower the creatinine concentration, by dilution; diuresis can artificially elevate it. Metabolic acidosis, particularly in the presence of hyperkalemia with elevated creatinine, should always prompt the clinician to determine the extent of renal acidosis. This is not easy. Hyperchloremia typically accompanies renal acidosis, but isotonic saline solution is frequently administered to patients with elevated creatinine under the mistaken belief that patients are less likely to develop hyperkalemia compared with BSSs.[78] A study of anephric patients undergoing renal transplantation demonstrated that patients treated with NS were more acidotic and hyperkalemic than patients treated with lactated Ringer's solution.[78] Hyperphosphatemia is a minor contributor to renal acidosis, and currently no tests are available to clinically identify the UMA, except by a process of exclusion. Hence, renal acidosis is usually diagnosed by identifying a widened AG, base deficit gap, or SIG, and excluding ketones and lactate. Usually the key decision step regarding RRT involves uncontrolled hyperkalemia. Renal acidosis can be temporarily controlled by administration of sodium bicarbonate (assuming the patient can clear CO_2), by increasing the SID. This may be necessary if the risk of delaying surgery exceeds the risk of delaying RRT. Note, however, in critical illness, delaying RRT was associated with a 4.7% increase in mortality at 90 days.[79]

Hyperchloremic Acidosis

Hyperchloremia has been a known cause of metabolic acidosis since the dawn of acid-base chemistry,[12] but due to difficulty in measuring serum Cl^- during most of the 20th century, hyperchloremia was largely ignored until recent decades. The extracellular space contains 110 to 130 g of salt. For a 70 kg male (ECF volume 18 L), this is approximately 58 g of Na^+ (3.22 g/L) and 65 g (3.62 g/L) of Cl^-. The average American ingests approximately 3 g or more of salt (NaCl) each day (2.3 g is recommended). To maintain the normal ratio of Na^+ to Cl^- (1.4:1 approximately), the body needs to excrete 30% more Cl^- than Na^+, and this is one of the major excretory roles of the kidney. This approximates to 15 to 20 mmol of Cl^- excretion per day; to maintain electrical neutrality Cl^- is excreted with ammonium (NH_4^+), a byproduct of nitrogen metabolism. In renal failure, Cl^- accumulates, and this is often the cause of the early metabolic acidosis associated with AKI. For decades, it has been hypothesized that elevated circulating levels of Cl^-, usually as a consequence of intravenous administration, may actually be nephrotoxic, due, presumably, to increased metabolic demands on the kidney. One liter of isotonic saline solution (0.9%, normal saline, NS) contains 9 g of salt, 3.5 g Na^+, and 5.5 g Cl^- (154 mmol/L of each). For a euchloremic patient (the human body does not store chloride, unlike, for example, calcium), this means that if 1 L of NaCl 0.9% is administered, most or all of the Cl^- must be excreted—an 8- to 10-fold increase in metabolic load for the kidney. Moreover, as NS has a SID of 0, elevated serum chloride is usually associated with a non-AG (hyperchloremic) metabolic acidosis.[80]

Hyperchloremic acidosis is a complication of renal tubular acidosis, which is caused by a defect in chloride excretion. The urine is relatively alkaline. Hyperchloremia also occurs when ureters have been re-implanted in the bowel after, for example, cystectomy, and excreted chloride is reabsorbed.

Are hyperchloremia and hyperchloremic acidosis clinically significant? As a cause of acidosis, hyperchloremia is less sinister than other causes: in a study of critically ill patients with various acid-base disorders, mortality was highest for lactic acidosis (56%); for SIG acidosis it was 39% and for hyperchloremic acidosis 29% ($P < .001$).[81] Nevertheless, hyperchloremia may result in clinically significant organ dysfunction. An observational study of 31,000 surgical patients comparing intravenous saline to intravenous BSS demonstrated significant outcome differences, favoring BSS.[82] Complications enhanced by the use of normal saline included postoperative infections, blood transfusions, and kidney injury requiring dialysis.

A hyperchloremic state may be associated with nephrotoxicity; saline infusion has been associated with reduced renal blood flow, renal vasoconstriction, reduced glomerular filtration, and splanchnic hypoperfusion.[83] In a relatively large before-and-after cohort study of patients treated in an Australian ICU, the use of chloride-rich fluids was associated with a 3.7% absolute increase in the risk for need in RRT relative to BSS.[84]

Two large randomized controlled trials looked at the use of isotonic saline solution versus BSS in emergency medicine patients[85] and critically ill patients.[86] Although the volume of fluid administered intravenously was relatively low, certainly in comparison with perioperative patients, in both studies there was approximately a 1% increase in renal complications. Whether this effect scales up with larger volumes will presumably be the subject of further study and meta-analysis.

NS solution, originally introduced by Hamburger in the 19th century and labelled "normal" due to flawed research, has been the most widely used intravenous fluid for over a century, despite minimal research demonstrating its clinical efficacy and safety.[87] As mounting research demonstrates that this particular fluid may be harmful, and with a variety of other balanced solutions available for clinical practice, the role of NS in perioperative medicine is highly questionable.

Perioperative Metabolic Alkalosis

Perioperative metabolic alkalosis is usually of iatrogenic origin. Overventilation of patients with chronic respiratory failure results in acute metabolic alkalosis because the presence of chronic compensatory alkalosis associated with chloride loss in urine has not been taken into account (Fig. 48.10). More frequently, metabolic alkalosis is associated with increased SID due to sodium gain. This abnormality results from the administration of fluids in which sodium is buffered by weak ions, citrate (in blood products), acetate (in parenteral nutrition), and, of course, bicarbonate. It is important to recognize that buffer ions such as citrate, acetate, gluconate, and lactate are, under normal conditions, rapidly cleared by the liver and do not contribute to acid-base balance. Sodium and chloride obey the law of conservation of mass. Sodium gain is "chloride sensitive" alkalosis, treated by administration of net loads of chloride—0.9% NaCl, potassium chloride, calcium chloride, and, occasionally, hydrogen chloride. It is important to correct chloride-sensitive alkalosis, as the normal compensatory measure is hypoventilation, increasing $PaCO_2$, which may lead to CO_2 narcosis and failure to liberate from mechanical ventilation.

Large volumes of BSSs are likely to cause metabolic alkalosis, due to dilution of A_{TOT} (principally hypoalbuminemia), a process that is curtained when using lactated Ringer's solution (Hartmann's) due to lower SID (20 mEq/L). The acquired hypoalbuminemic alkalosis is of undetermined clinical significance.

Another cause of metabolic alkalosis in perioperative patients reflects loss of chloride-rich fluids from the gastrointestinal tract. Gastric juice contains HCl, which, when lost as a result of continuous suctioning or vomiting, obeys the law of conservation of mass and leads to alkalosis.

Perioperative fluid therapy remains highly controversial. Isotonic fluids are usually administered due to fear of cerebral edema associated with stress-induced water retention. However, this results in large amounts of solute, in particular sodium and chloride, accumulating in the extravascular space. Acquired hypernatremia is associated with adverse clinical outcomes and is very difficult to treat.[88] BSSs appear safer than NS, but large-volume administration of these resuscitation fluids are also associated with worse outcomes.[89]

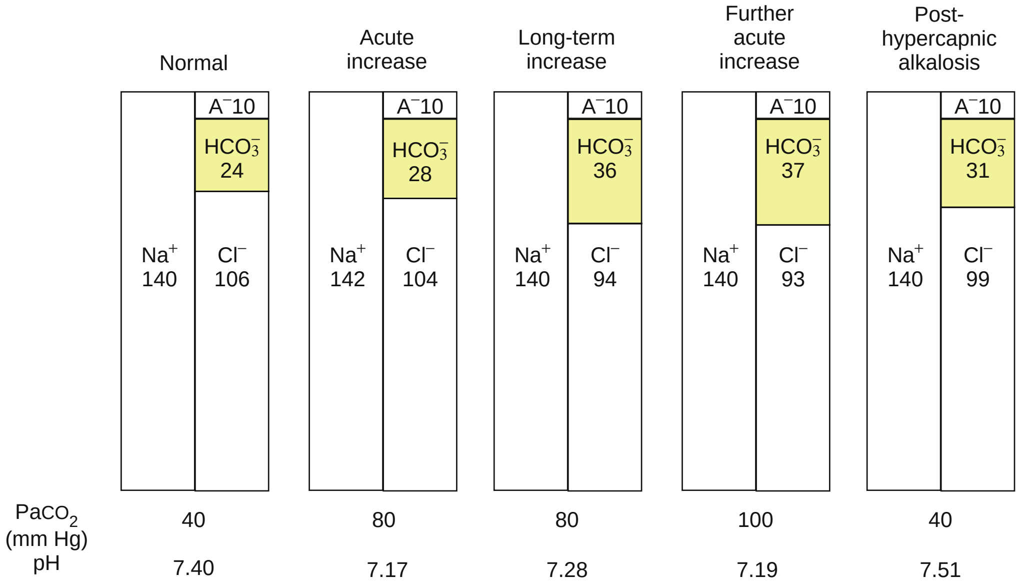

Fig. 48.10 Changes in Acid-Based and Electrolyte Composition in Patients With Respiratory Acidosis. *Left to right*, the panels depict normal acid-base status; adaptation to an acute rise in the partial pressure of arterial carbon dioxide ($PaCO_2$) to 80 mm Hg; adaptation to a long-term rise in $PaCO_2$ to 80 mm Hg; superimposition of an acute further increment in $PaCO_2$ (to a level of 100 mm Hg) in the same patient; and post-hypercapnic alkalosis resulting from an abrupt reduction in $PaCO_2$ to the level of 40 mm Hg in the same patient. A^-denotes unmeasured plasma anions, and the numbers within the bars give ion concentrations in millimoles per liter. (Modified from Adrogué HJ, Madias NE. Management of life-threatening acid-base disorders. First of two parts. *N Engl J Med*. 1998;338[1]:26–34.)

ACID-BASE DISTURBANCES IN CRITICAL ILLNESS

Critically ill patients may have many confounding acid-base disturbances that are not evident when only a single quantitative measure, such as base deficit, is employed. Patients will frequently have perturbations of PCO_2, SID, and A_{TOT}, and significant pathology may be overlooked due to apparently normal blood gas results.[90]

The most common single disturbance in acid-base chemistry in critically ill patients is hypoalbuminemia.[24] This abnormality is ubiquitous and causes a metabolic alkalosis of unpredictable magnitude. Hypoalbuminemia may mask significant alterations in SID, for example lactic or renal acidosis. Therefore, when the AG is used in critically ill patients it should be corrected for albumin.[26] Similarly, the use of base deficit to predict lactate is unreliable in critical illness, particularly in patients undergoing secondary deterioration.[25] Further, prolonged respiratory failure, with associated hypercarbia, leads to additional metabolic alkalosis due to chloride loss in urine (see Fig. 48.10)[91] Kidney injury is associated with accumulation of metabolic by-products, phosphate, renal anions, chloride, and other UMA, leading initially to metabolic acidosis. However, late polyuric renal failure may be associated with significant contraction alkalosis, due to loss of sodium, potassium, and free water.

Critically ill patients are vulnerable to significant changes in SID and free water. Nasogastric suctioning causes chloride loss, diarrhea leads to sodium and potassium deficits. Surgical drains placed in tissue beds may remove fluids with varying electrolyte concentrations (the pancreatic bed, for example, secretes fluid rich in sodium). Fever, sweating, evaporation from denuded tissue, and inadequately humidified ventilator circuits all can lead to large-volume insensible loss and contraction alkalosis.

Infusions administered to patients may be responsible for unrecognized alterations in serum chemistry. Many antibiotics, for example piperacillin-tazobactam, are diluted in sodium-rich solutions. Others, such as vancomycin, are administered in large volumes of free water (5% dextrose). Lorazepam is diluted in propylene glycol, large volumes of which will cause metabolic acidosis similar to that seen with ethylene glycol.[92]

Continuous renal replacement therapy (CRRT) is used in critical illness to hemofilter and hemodialysis patients who are hemodynamically unstable. Rocktaschel[93] and colleagues have demonstrated that CRRT resolved the acidosis of acute renal failure by removing strong ions and phosphate. However, in the presence of hypoalbuminemia, use of dialysis to correct a metabolic acidosis may unmask a metabolic alkalosis due to hypoalbuminemia. CRRT is not an effective treatment for lactic acidosis or ketoacidosis.

Other seemingly innocuous therapies may cause significant disturbances to acid-base balance. Loop diuretics, such as furosemide, are often administered to critically ill patients. These agents preferentially excrete water over electrolytes and provoke a contraction alkalosis. Similarly, carbonic anhydrase inhibitors such as acetazolamide may be used to treat patients with hypochloremic metabolic alkalosis or respiratory alkalosis by decreasing the plasma SID. This effect is completely explained by the increased renal excretion ratio of sodium to chloride, resulting in an increase in serum chloride.[94]

Neurosurgical patients are vulnerable to a variety of acid-base disturbances as a result of osmotherapy or from disturbances caused by brain injury. Most commonly, NS solution is administered to these patients and results in hyperchloremic acidosis.[95] Diabetes insipidus (DI) is a frequent complication of severe head injury, particularly when the patient is progressing toward brain death. DI is caused by damage to the pituitary and/or the hypothalamus and results in a loss of antidiuretic hormone (ADH) secretion. Absent ADH, the kidney is unable to concentrate the urine and a massive diuresis follows. The disorder is characterized by an increase in plasma osmolality in the presence of a low urinary osmolality. DI will typically manifest as a contraction alkalosis. The treatment is hormonal replacement with either vasopressin or desmopressin.

TREATING ACID-BASE DISTURBANCES

In general, in acute illness and perioperative medicine, acid-base disturbances are clinical indicators of disease processes that are more harmful than hydrogen ion abnormalities themselves. Correcting the pH is usually unlikely to resolve the problem, except in certain circumstances, such as hyperkalemia in AKI, where acidosis is the major cause of the problem.

The treatment of acid-base abnormalities is determined by whether the acids, in particular, are organic or mineral acids. Organic acids can be metabolized, excreted, or dialyzed from the body. Diabetic and nondiabetic ketoacidosis are treated primarily with insulin, intravenous fluid, and glucose. The ketoacids causing metabolic acidosis are metabolized by the liver. AKI is treated with dialysis and ultrafiltration, which directly removes UMA. Surprisingly, there are no clear guidelines regarding the optimal timing of initiation of RRT,[79,96] particularly in the perioperative period.[97]

For decades, sodium bicarbonate ($NaHCO_3^-$) has been used to "correct" acidosis. The sodium component, as a strong anion, widens the SID and is alkalizing. Simultaneously, the bicarbonate moiety provides buffer for hydrogen ions, generating CO_2, which is presumably excreted from the body by increased alveolar ventilation. In respiratory failure, sodium bicarbonate will worsen respiratory acidosis despite increased SID. CO_2 also enters cells and may cause intracellular acidosis, the clinical significance of which is unclear.[98]

$NaHCO_3^-$ is commonly used to treat hyperchloremic acidosis. For patients with renal tubular acidosis, this involves long-term treatment with sodium bicarbonate tablets and chloride restriction. In acquired hyperchloremic acidosis, intravenous sodium bicarbonate corrects the base deficit,[99] but the benefit is unclear. The major drawbacks of $NaHCO_3^-$ therapy include sodium and volume overload, metabolic alkalosis, hypertension, and hypocalcemia.

Sodium bicarbonate therapy has been extensively studied in lactic acidosis and circulatory shock.[100] A recent randomized trial of 389 critically ill patients with metabolic acidosis compared the administration of 4.2% (hypertonic) $NaHCO_3^-$ to keep pH above 7.3, up to a maximum of 1000 mL in the first 24 hours, versus no intervention.[101] Although there were no differences in the primary outcome—28-day mortality—the patients who received $NaHCO_3^-$ had a lower incidence of AKI and requirement for RRT. It is unclear why there was a reduction in the need for RRT. Perhaps the reduction in acidosis delayed the decision to start RRT and resulted in the intervention being avoided completely,[96] or reversal of acidosis reduced vasopressor requirement and improved kidney blood flow; but this is merely speculation. Previous meta-analyse have failed to demonstrate benefit from $NaHCO_3^-$ therapy,[102] presumably due to the paucity of available research. Until larger multicenter trials have been conducted, $NaHCO_3^-$ therapy should be used with caution for treatment of metabolic acidosis, due to circulatory shock or ketoacidosis. It is also unlikely that $NaHCO_3^-$ therapy benefits perioperative patients at risk for postoperative kidney failure.[103]

Metabolic alkalosis is rarely seen in elective perioperative care. It is most likely encountered when unmasked by overventilation of patients who chronically retain CO_2. Minute ventilation should be reduced. Critically ill patients may have metabolic alkalosis due to chloride deficit, free water deficit, or hypoalbuminemia. Contraction alkalosis is treated by correcting the free water deficit using the formula below:

$$\begin{aligned}\text{Free water deficit} = 0.6 \times \text{patient's weight in kg} \\ \times (\text{patient's sodium}/140 - 1)\end{aligned}$$

Hypochloremic alkalosis should be treated by correcting the chloride deficit using NS or LR.

There is no evidence that correcting hypoalbuminemia is of clinical benefit for the majority of patients.[104] Respiratory alkalosis usually results from anxiety or pain. Short-term therapy, such as CO_2 rebreathing, should be followed by treating the underlying problem—for example with opioids or benzodiazepines.

Hypercarbic acidosis may be encountered in the perioperative period due to deliberate[105] or inadvertent hypoventilation. It is also associated with elevated dead space ventilation as seen in ARDS. In general, acute respiratory acidosis is well tolerated and can be easily reversed by increasing minute ventilation. However, in ARDS, a high tidal volume and transpulmonary pressures result in ventilator induced lung injury (VILI) and increased mortality.[106] Consequently, hypercarbia must be tolerated by the physician and patient ("permissive hypercarbia") or CO_2 removed by an extracorporeal circuit.[107]

Summary

Much of the confusion regarding acid-base chemistry relates to the attempt to apply observational approaches, such as that of Henderson-Hasselbalch and Schwartz and Brackett, to the entire spectrum of pathophysiologic processes. The use of physical chemistry principles has permitted easier explanation of acid-base balance, and tools to apply to a wide variety of clinical situations. This does not suggest that the "traditional" approach is incorrect, merely that it looks at a mirror image of that proposed by Stewart, Fencl, and others. All acid-base disorders can be explained in terms of SID, A_{TOT}, and PCO_2. This is important to anesthesiologists, who may significantly impact acid-base balance with our choice of fluids and mechanical ventilation strategy.

Patient Blood Management: Transfusion Therapy

MATTHEW DUDLEY, RONALD D. MILLER, and JOHN H. TURNBULL

KEY POINTS

- Blood transfusion is safer now than at any other time in history. Advances in donor screening, improved testing, automated data systems, and changes in transfusion medicine practices account for these increases in safety.
- Although the overall condition of the patient is of prime importance, hemoglobin (Hb) values remain a primary component for transfusion decisions with the use of either a restrictive or liberal strategy. In general, a transfusion trigger of 6 to 8 g/dL Hb (restrictive strategy) can be tolerated by patients.
- Preoperative anemia is an independent, and potentially modifiable, risk factor for postoperative morbidity and mortality.
- The term *patient blood management* has become synonymous with appropriate transfusion strategy.
- The addition of plasma and sometimes platelets to packed red blood cells (PRBCs) is described by the term *transfusion ratios.* For example, 2 units of plasma with 1 unit of platelets with 1 unit of PRBCs would be 2:1:1.
- Infectivity of blood is no longer a major cause of transfusion-related morbidity and mortality. Transfusion-related acute lung injury is the leading cause of transfusion-related mortality.
- Fresh whole blood has gained renewed interest as a choice in patients with major blood loss and related coagulopathy (see also Chapter 50).
- Although storage lesions of red blood cells increase over time, there is no evidence that blood stored for short periods compared with moderately long periods of time contributes to worse clinical outcomes. However, as newer solutions extend the shelf-life of blood, this may need continued evaluation, particularly in high-risk groups.

Transfusion of human-derived blood products is one of the most common procedures in modern medicine, often proving life-saving. In a recent analysis of electronic medical records from hospitals in the United States, blood transfusion occurred for 12.5% of hospitalized inpatient encounters, with red blood cells (RBCs) being the most commonly transfused component, followed by platelets and plasma.[1] Transfusion is not without risk, and the anesthesiologist must weigh the risks and benefits of providing or withholding transfusion therapy for individual patients in specific clinical settings. This chapter focuses on the physiology and pathology of transfusion medicine with particular attention to the acquisition, processing, storage, indication for, and risk of blood therapy in the perioperative period.

Evolution and Recent History of Blood Transfusion Therapy

THE 1960S

Transfusion medicine has undergone enormous changes in the last 60 years, but the consensus of whether to use whole blood, its components, or both has vacillated every decade or so. In the 1960s, most blood given was in the form of whole blood, whereas fresh frozen plasma (FFP) was available for the treatment of coagulopathies.[2,3]

THE 1970S THROUGH THE 1980S

Transfusion therapy was characterized in this period by "giving the patient only the component of blood that was needed." Component transfusion therapy rather than whole blood transfusion was the standard of care. For example, if the patient was anemic, only packed red blood cells (PRBCs) would be transfused, or if thrombocytopenia existed, only platelet concentrates would be given. Caution regarding administration of blood transfusions increased during this time period in part because of concern regarding the infectivity of blood (e.g., hepatitis and human immunodeficiency virus [HIV]). Furthermore, individual clinical decisions regarding blood transfusions were and continue to be monitored by local hospital transfusion committees (as required by regulatory agencies of various countries including the United States). These committees have the responsibility of monitoring the individual and institutional transfusion practices by evaluating clinical appropriateness of transfusion triggers.[4]

1990S THROUGH THE 2000S

With improved screening techniques for HIV and other blood-borne pathogens during this decade, the incidence of blood transfusion–related infectious disease transmission decreased 10,000-fold. The focus of blood product safety now shifted to *noninfectious serious hazards of transfusion*.[5] These hazards include hemolytic transfusion reactions, transfusion-related acute lung injury (TRALI), and transfusion-associated circulatory overload (TACO), to name a few. With an increased awareness of the potential morbidity and mortality associated with blood product administration, research focused on the concept of liberal versus restrictive blood transfusion strategy. Attention now turned to balancing the threats posed by two independent (yet related) risk factors of patient outcome—anemia and transfusion.

Although the strategy of specific component therapy was still prominent, the concept of reconstituted "whole blood" was introduced during this decade. Led by trauma hospitals and the military, FFP and platelets were transfused along with PRBCs, resulting in a transfusion ratio that was similar to that of whole blood.[6,7] Because the concept of transfusing components that reconstitute whole blood rouses the prior practice of transfusing whole blood, that concept is being reexamined[8] again in the literature and may yet prove beneficial in patients with life-threatening bleeding.[9,10]

2010 TO THE PRESENT

The 2010s saw a shift away from simply correcting anemia and coagulopathy, to a more patient-centered, multipronged approach to transfusion medicine. As a result, the term *patient blood management (PBM)* has become synonymous with modern, evidence-based transfusion medicine.[11] The Society for the Advancement of Blood Management defines PBM as "the timely application of evidence-based medical and surgical concepts designed to maintain hemoglobin concentration, optimize hemostasis and minimize blood loss in an effort to improve patient outcome." [12] PBM recognizes transfusions are but a temporary solution to an often complex, multifactorial process that requires attention to the underlying cause of anemia.[13]

Integration of PBM into clinical pathways has reduced the reliance on allogenic blood product transfusion as the only means to avoid anemia and likely explains the continued decrease in transfusions noted in U.S. hospitals over the last decade.[14] In a recent retrospective analysis, implementation of a PBM system with a reduced transfusion threshold from 8 g/dL to 7 g/dL Hb in orthopedic surgical patients reduced the use of erythrocytes by 32% while improving clinical outcomes. Most notably, patients 65 years and older demonstrated the most improved clinical outcomes, including 30-day readmission rates.[15] Comprehensive PBM programs also can include evaluation of preoperative anemia, clinical decision support, educational efforts, improved surgical techniques, and blood conservation strategies.

PBM in many countries has been facilitated by computerized data systems[16] and supply guidelines.[17] A limitation of most of the PBM publications is that they describe mostly nonbleeding, anemic patients and the decision to initiate transfusion. Very little information addresses what guidelines should be used for repetitive transfusions. The anesthesia provider offers insight into these issues and can provide guidance as to how PBM fits into the perioperative clinical environment.

Blood Procurement

SOURCE OF DONORS

Significant global disparities exist regarding access to "safe" blood, or blood that is properly collected and tested. According to World Bank definitions, low- and middle-income countries collect 53% of all blood donations worldwide, yet represent 81% of the world's population. In addition, the prevalence of transfusion-transmissible infections in blood donations from low- and middle-income countries is significantly higher than those from high-income countries, yet low-income countries have less access to basic quality screening procedures.[18] Another issue, particularly in low-income countries, is incentivized donors. The World Health Organization's (WHO) decision-making body, the World Health Assembly, has issued resolutions and consensus statements that emphasize the need for all member states to develop national blood systems based on voluntary, unpaid donations as a means to ensure a safe, secure, and sufficient supply of blood products.[19] Some experts have suggested that offering economic incentives or rewards to donors should be seriously considered,[20] because limited empirical research exists to support the assumption that incentivized donations, including noncash incentives, either improve recruitment of donors or pose a risk to blood product safety.[21] However, the WHO strongly defends voluntary nonremunerated blood donation as a vehicle to a safer blood supply and increased donor participation.[22]

In the United States, the Food and Drug Administration's (FDA) Center for Biologics Evaluation and Research provides the regulatory oversight for blood banks and donation centers, with most voluntarily obtaining accreditation from the AABB (formerly, American Association of Blood Banks). In Europe, the European Commission sets standards for blood products and their components in the European Blood Directive (Directive 2002/98/EC). These regulatory and professional societies set standards with regard to the donation, collection, testing, processing, storage, and distribution of products.

In the United States, those over the age of 16 and who weigh at least 110 pounds are eligible for screening for potential blood donation. Vital signs are assessed, including temperature, heart rate, and blood pressure. Hb levels are measured, with minimum cutoffs of 13 g/dL for men and 12.5 g/dL for women. Blood is collected either as whole blood and separated by centrifugation or by apheresis, in which only specific components are collected while other components are returned to the donor. An outline of the separation scheme by which various blood components are derived is shown in Fig. 49.1. Apheresis is particularly helpful in donors with blood type AB, as they represent a rare blood type yet serve as the universal plasma donor. As recipients, patients with blood type AB rarely require AB specific blood, as they can be transfused with any type of red cell. Therefore, if plasma is collected from AB donors while

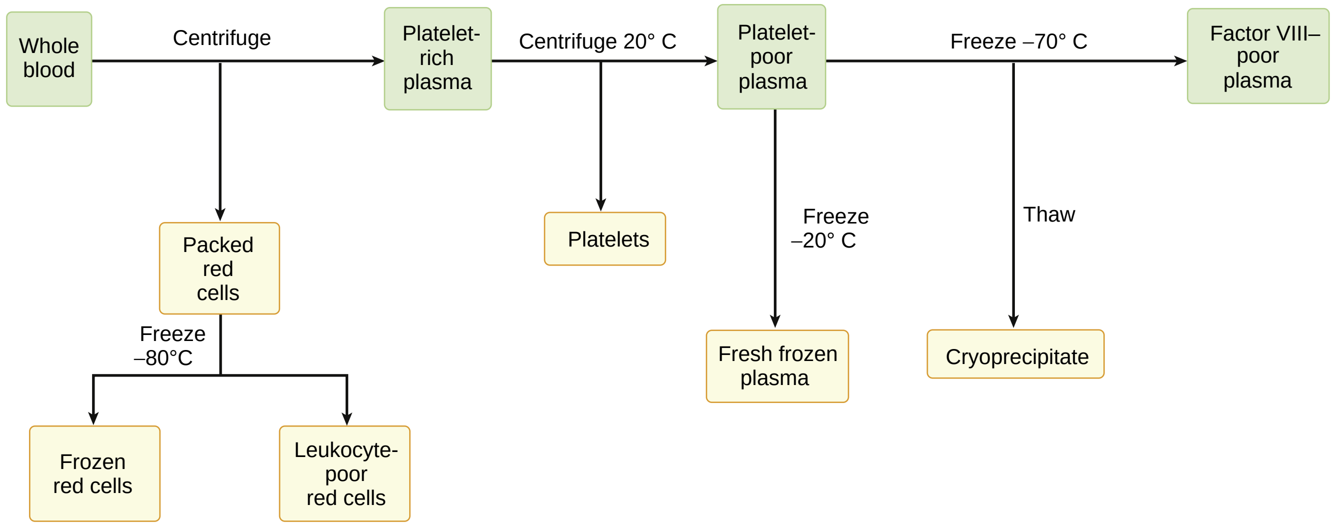

Fig. 49.1 Scheme for separation of whole blood for component therapy.

red cells are immediately returned, this may allow for more frequent plasma donation from this small but vitally important group of donors.

TRANSFUSION-TRANSMISSIBLE INFECTIONS

Donor screening attempts to reduce the risk of a transfusion-transmissible disease and to protect the donor from an adverse reaction due to donation. Deferment based on medical history includes those considered to be in high-risk categories for potential transmission of an infectious agent, including those with a significant travel history, history of injection drug use, recent tattoos, or men who have had sex with men (MSM) in the previous 12 months. The latter deferment category has been controversial in recent years, given the changing epidemiology of the HIV epidemic and improved screening methods. In this population, some advocate for reducing the time interval between potential exposure and donation to 3 months.[23]

The use of more sensitive screening tests in conjunction with changes in transfusion medicine practices have made infectious risks quite rare. The FDA requires blood products to be tested for hepatitis B and C, HIV (types 1 and 2), human T-lymphotropic virus (HTLV; types 1 and 2), and *treponema pallidum* (syphilis), West Nile virus, and Zika virus. Testing is recommended for *Trypanosoma cruzi* (Chagas disease) for first-time donors. Historically, the FDA has published tables on the risks for infectivity, Table 49.1 but because the rates are so infrequent, the last tables published were for data from 2011.

Several blood-safety changes made between the years of 1982 and 2008 have decreased the risk for disease transmission by allogenic blood so that the demand for autologous blood has declined as well. The West Nile virus story illustrates how rapidly our blood banks can respond. In 2002, West Nile virus caused the largest outbreak of arboviral encephalitis ever recorded in the United States (i.e., approximately 4200 patients). Twenty-three cases of transfusion-transmitted infections resulted in seven deaths. In 2003, testing became available that now makes that infection very rare (see Table 49.1). The FDA's response to the 2015 to 2016 Zika virus outbreak was similarly swift—the blood supply was immediately shifted from areas with low risk of infections to areas of known infection; authorization for screening tests was issued within months, and universal screening with a qualitative nucleic acid test (NAT) for the detection of Zika virus ribonucleic acid (RNA) was mandated.[24]

TABLE 49.1 Percentage Risk of Transfusion-Transmitted Infection With a Unit of Screened Blood in the United States

Infection	Risk	Window Period (Days)
Human immunodeficiency virus-1 and -2	1:1,476,000	5-6
Human T-lymphotropic virus (HTLV-II)	1:2,993,000	51
Cytomegalovirus (CMV)	Infrequent with leukocyte-reduced components	
Hepatitis C virus (HCV)	1:1,149,000	3-4
Hepatitis B virus (HBV)	1: 280,000	24
Hepatitis A virus (HAV00)	1:1,000,000	
Bacteria red blood cells	1:1,000 with septic reaction in 1:500,000	
Pheresis platelets (with early aerobic culture)		
Parasites: Babesia and malaria	<1:4,000,000	7-14
West Nile virus (WNV)	1/1,100,000	?
Acute hemolytic transfusion reactions	1:38,000-1:70,000	

Data from AABB: *AABB Technical Manual,* 17th ed. 2011, AABB; and Fiebig ER, Busch MP. Infectious risks of transfusions. In: Spiess BD, Spence RK, Shander A, eds. *Perioperative Transfusion Medicine.* Philadelphia: Lippincott Williams & Wilkins; 2006.

The changes in blood transfusion testing can be appreciated when comparing tests used in 1998 (Box 49.1) with those used in 2018 (Table 49.2. The use of nucleic acid technology has decreased the window of infectivity (i.e., time from being infected to a positive test result), which is a major reason for the decrease in infectivity with hepatitis, HIV, West Nile virus, and Zika virus.

BOX 49.1 **Infectious Disease Testing for Blood Transfusions**

1. Discontinue serum alanine aminotransferase testing
2. Hepatitis C antibody testing
3. Antibody to hepatitis B core antigen
4. Human immunodeficiency virus (HIV) type 1
5. HIV-2
6. HIV Ag (p24 antigen)
7. Human T-cell lymphotropic virus (HTLV) types 1 and 2
8. Serologic test for syphilis

TABLE 49.2 Tests Used for Detecting Infectious Agents in All Units of Blood: 2018

Virus	Genetic Testing	Antibody To
Human immunodeficiency virus (HIV)	Nucleic acid technology	HIV-1, HIV-2
Hepatitis C virus (HCV)	Nucleic acid technology	HCV
Hepatitis B virus (HBV)	Nucleic acid technology	Anti-HBc, HBsAg
Human T-cell lymphotropic, virus (HTLV)		HTLV-1, HTLV-2
West Nile virus	Nucleic acid technology	
Zika virus	Nucleic acid technology	

Posttransfusion Hepatitis

When blood transfusions became a reality in the 1940s, viral hepatitis was recognized as a major complication. The concern is primarily with hepatitis B, C, and, rarely, D, which are parenterally transmitted viruses. Before 1985, the overall incidence of posttransfusion hepatitis ranged from a low of 3% to a high of 19%, depending on the institution and the location (e.g., donors from large cities have a more frequent incidence of the hepatitis virus). In most areas, the incidence of hepatitis has ranged from 3% to 10%. Ninety percent of posttransfusion hepatitis is caused by the hepatitis C virus. Fewer than a third of these patients develop jaundice.[25] To determine their ultimate fate, Tong and colleagues[25] monitored 131 patients with chronic posttransfusion hepatitis C for several years and found the following incidence of signs, symptoms, and conditions:

- Fatigue (67%)
- Hepatomegaly (67%)
- Chronic hepatitis (23%)
- Chronic active hepatitis (51%)
- Hepatocellular carcinoma (11%)

It was found that 20 patients had died of the following:

- Complications of cirrhosis (8 patients)
- Hepatocellular carcinoma (11 patients)
- Chronic active hepatitis-pneumonia (1 patient)

Even today, patients with hepatitis C and apparent recovery from the acute infection may go on to develop cirrhosis and hepatocellular carcinoma. Several antiviral therapies, such as Mavyret (glecaprevir-pibrentasvir), Harvoni (ledipasvir-sofosbuvir), Epclusa (sofosbuvir-velpatasvir), and Vosevi (sofosbuvir-velpatasvir-voxilaprevir), now exist that may stop progression and even cure infection from certain genotypes of hepatitis C. However, any person who has ever tested positive for hepatitis B or hepatitis C, at any age, is currently ineligible to donate blood.[26]

Cytomegalovirus

Asymptomatic chronic infection with cytomegalovirus (CMV), a double-stranded DNA virus belonging to the herpesviridae family, is common enough in healthy adults that some view CMV as normal flora. Infection with the CMV virus is limited to humans, requires contact with the body fluids of a previously infected individual, survives best within cells, and persists in its latent form in the monocytes of people with antibody evidence of previous exposure infection. Fortunately, the primary concern is recipients who are at risk because of pregnancy (multiple), immaturity, or immunosuppression. CMV seroconversion usually occurs in subsets of patients receiving multiple transfusions. CMV causes a heterophil antibody-negative response that closely resembles infectious mononucleosis in many respects. An infectious mononucleosis–like syndrome that can occur 1 to 2 months after open-heart surgery is known as the *postperfusion syndrome* or *posttransfusion mononucleosis*.[27] The evidence for transmission of CMV is most convincing when the recipient changes from a seronegative state before transfusion to a seropositive state accompanied by the mononucleosis-like illness several weeks after transfusion.

Transfusion-transmitted CMV can cause significant clinical problems in certain patient populations, such as premature neonates, allograft recipients, and patients post splenectomy.[28] To prevent infection in high-risk populations, use of leukocyte-reduced blood, use of frozen deglycerolized RBCs, and screening for CMV antibody negative donors have been recommended (see the section on leukoreduction and irradiation of blood transfusions). Wilhelm and associates[29] concluded that it is not necessary to provide blood products from CMV-seronegative donors for most patients who receive blood transfusions, because the risk for seroconversion is approximately 0.14% overall, or 0.38% per unit of seropositive donor blood. They do recommend continuing to use CMV-seronegative blood to prevent CMV infection in preterm and newborn infants. Plasma components, such as FFP and cryoprecipitate, and leukoreduced components from seropositive donors are considered to be CMV safe.

Zika Virus

More recently, transfusion-transmissible Zika virus infection has been of concern.[30] Transmitted by mosquitos, Zika virus infection is associated with Guillain-Barre syndrome[31] and microcephaly in newborns whose mothers were infected during pregnancy.[32] Although these manifestations of Zika virus infection are striking, 80% of infected persons are asymptomatic, and thus pose a potential threat to the blood supply. As a result, the FDA issued guidance that all donations collected in the United States be tested for Zika virus using NAT.[33]

TABLE 49.3 Infectious Diseases Theoretically Transmissible by Blood Transfusion for Which No Test Is Available: 2004

Disease	Risk
Malaria	<1 million in the United States
Severe acute respiratory syndrome (SARS)	Unknown
Variant Creutzfeldt-Jakob disease	Three potential cases in the United Kingdom

Other Transfusion-Associated Infectious Diseases

Although many other infectious diseases can theoretically be transmitted by blood transfusion, only a few are of real concern. They include *Yersinia enterocolitica* infection, syphilis, malaria, Chagas disease, variant Creutzfeldt-Jakob disease, parvovirus B19, and severe acute respiratory syndrome (SARS; Table 49.3).

During the late 1980s, Tripple and colleagues[34] described seven cases of fatal transfusion-associated *Y. enterocolitica* sepsis. These investigators also reviewed the literature and found 26 cases of gram-negative bacterial sepsis with whole blood or PRBCs. *Y. enterocolitica* is a bacterium that can cause mostly mild gastrointestinal problems. However, in severe cases, sepsis and death can occur. Unfortunately, storage of blood at 4°C in phosphate buffer enhances its growth.

Fortunately, posttransfusion syphilis is unlikely because the infective agent cannot survive during storage at 1°C to 6°C. Platelet concentrates are the blood component most likely to be implicated because they commonly are stored at room temperature.

Posttransfusion malaria has never been a significant cause of blood recipient morbidity. Nevertheless, malaria can occur, especially if blood donors at risk for harboring parasites are not excluded. Consequently, blood banks thoroughly question donors for history of travel or migration from areas where malaria is endemic.

Even though there are no cases of variant Creutzfeldt-Jakob disease from blood transfusions, the virus can be transmitted by blood in animal models and stringent donor policies based on travel and residence in England or other countries in Europe are in place.

Like malaria, there are other infectious agents that can transmit disease through blood transfusions, but there are no available blood testing methods for these cases (see Table 49.3). Without a specific diagnostic test, screening with restrictive donor criteria is used. For example, in 2003 in the United States, donors with suspected SARS or who traveled to certain countries in Southeast Asia would not be accepted.

BIOCHEMICAL CHANGES IN STORED BLOOD

Units of blood collected from donors are usually separated into components (e.g., RBCs, plasma, cryoprecipitate, and platelets; see Fig. 49.1). Citrate phosphate dextrose adenine-1 (CPDA-1) is an anticoagulant preservative that is used for blood stored at 1°C to 6°C. Citrate prevents clotting by binding Ca^{2+}. Phosphate serves as a buffer, and dextrose is a red cell energy source, allowing the RBCs to continue glycolysis and maintain sufficient concentrations of high-energy nucleotides (adenosine triphosphate [ATP]) to ensure continued metabolism and subsequent viability during storage. The addition of adenine prolongs storage time by increasing the survival of RBCs, allowing them to resynthesize the ATP needed to fuel metabolic reactions. This extends the storage time from 21 to 35 days.[35] Without adenine, RBCs gradually lose their ATP and their ability to survive after transfusion. Finally, storage at 1°C to 6°C assists preservation by reducing the rate of glycolysis approximately 40 times the rate at body temperature.

The shelf life of PRBCs can be extended to 42 days when AS-1 (Adsol), AS-3 (Nutricel), or AS-5 (Optisol) is used.[36,37] Adsol contains adenine, glucose, mannitol, and sodium chloride (NaCl). Nutricel contains glucose, adenine, citrate, phosphate, and NaCl. Optisol contains only dextrose, adenine, NaCl, and mannitol. On a national level, 85% of RBCs are collected in AS-1. In Europe, a solution similar to AS-1 containing saline, adenine, glucose, and mannitol is used. As of 2015, the FDA approved a new additive solution, AS-7, which increases storage time to at least 56 days; however, the solution is not yet commercially available in the United States.[38]

The hematocrit (Hct) of the transfused product depends on the storage method. When CPDA is the anticoagulant used, the Hct is greater than 65%, because most of the plasma is removed, and the resulting volume is approximately 250 mL. When AS-1 is used, most of the plasma is also removed, but 100 mL of storage solution is added, resulting in an Hct of 55% to 60% and volume of 310 mL.[39] The duration of storage is set by U.S. federal regulation and is based on the requirement that at least 70% of the transfused RBCs remain in circulation for 24 hours after infusion.

During storage of whole blood and PRBCs, a series of biochemical reactions occur that alter the biochemical makeup of blood and account for some of the complications. Collectively, these are known as *red cell storage lesions* and may be responsible for the organ injury associated with red cell transfusion. During storage, RBCs metabolize glucose to lactate; hydrogen ions accumulate, and plasma pH decreases, while increases in oxidative damage to lipids and proteins are noted. The storage temperature of 1°C to 6°C inhibits the sodium-potassium pump, resulting in a loss of potassium ion (K^+) from the cells into the plasma and a gain of intracellular sodium.[40] Although K^+ concentrations appear elevated in 35-day stored RBC concentrates, the total plasma volume in the concentrates is only 70 mL, so total K^+ is not markedly elevated. Over time, there are progressive decreases in RBC concentrations of ATP, nitric oxide (NO), and 2,3-diphosphoglycerate (2,3-DPG).

The osmotic fragility of RBCs increases during storage, and some cells undergo lysis, resulting in increased plasma Hb levels. In addition, deformability of RBCs appears impaired in patients who receive allogenic blood cell transfusion, potentially resulting in micro-occlusive events.[41] Frank and associates[42] studied the blood of patients undergoing posterior spinal fusion surgery and found that increased duration of blood storage was associated with decreased RBC deformability, which was not "readily" reversible after transfusion. They speculated that these deformed cells may be defective in delivering oxygen (O_2) to

TABLE 49.4 Properties of Whole Blood and Packed Red Cell Concentrates Stored in CPDA-1

	DAYS OF STORAGE		
Variable	**0**	**35 (Whole Blood)**	**35 (Packed Cells)**
pH	7.55	6.73	6.71
Plasma hemoglobin (mg/dL)	0.50	46.00	246.00
Plasma potassium (mEq/L)	4.20	17.20	76.00
Plasma sodium (mEq/L)	169.00	153.00	122.00
Blood dextrose (mg/dL)	440.00	282.00	84.00
2,3-Diphosphoglycerate (μM/mL)	13.20	1.00	1.00
Percent survival*	—	79.00	71.00

*Percent recovery of O_R-tagged red blood cells at 24 h.
CPDA-1, Citrate phosphate dextrose adenine-1.

the cells and concluded that both the "age of blood storage" and "amount" of blood given should be considered when giving blood (Table 49.4).

CHANGES IN OXYGEN TRANSPORT

RBCs are transfused primarily to increase transport of O_2 to tissues. Theoretically, an increase in the circulating red cell mass will produce an increase in O_2 uptake in the lungs and a corresponding increase in O_2 delivery to tissues, but RBC function may be impaired during preservation, making it difficult for them to release O_2 to the tissues immediately after transfusion.

The O_2 dissociation curve is determined by plotting the partial pressure of O_2 (PO_2) in blood against the percentage of Hb saturated with O_2 (Fig. 49.2). As Hb becomes more saturated, the affinity of Hb for O_2 also increases. This is reflected in the sigmoid shape of the curve, which indicates that a decrease in the arterial partial pressure of oxygen (PaO_2) makes considerably more O_2 available to the tissues. Shifts in the O_2 dissociation curve are quantitated by the P_{50}, which is the partial pressure of O_2 at which Hb is half saturated with O_2 at 37°C and pH 7.4. A low P_{50} indicates a left shift in the O_2-dissociation curve and an increased affinity of Hb for O_2. The left shift of the curve indicates that a lower than normal O_2 tension saturates Hb in the lung, but the subsequent release of O_2 to the tissues is more difficult, as it occurs at a lower than normal capillary O_2 tension compared with an unshifted curve. In other words, the increased affinity of Hb for O_2 makes it more difficult for Hb to release O_2 to hypoxic tissues. This leftward shift is likely a result of decreased levels of 2,3-DPG in stored RBCs, which can remain low for up to 3 days posttransfusion.[43]

Many of the advances in blood processing and storage are centered on the material of the collections and storage containers.[44] Innovative methods of storing blood are being developed. For example, storing blood in an electrostatic field of 500 to 3000 V decreases hemolysis and attenuates the decrease in pH associated with prolonged storage.[45] Current blood collection and storage systems are made of disposable plastic; these materials must have properties compatible with collection, processing, storage, and administration. Polyvinylchloride (PVC) with use of different plasticizers is commonly used because it is nontoxic, has flexibility, mechanical strength, water impermeability, resistance to temperature extremes for sterilization and freezing, compatibility with blood components, and selective permeability for cellular gas exchange.

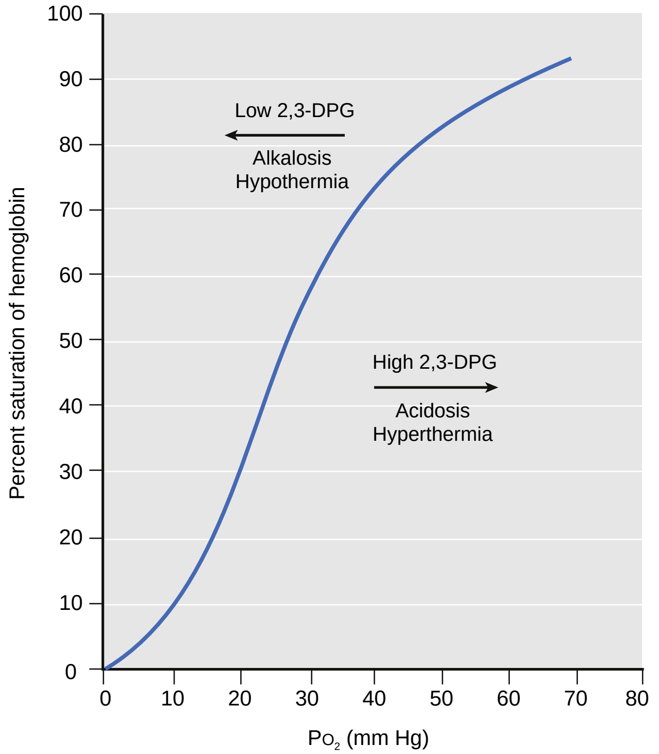

Fig. 49.2 Factors that shift the oxygen dissociation curve. *2,3-DPG,* 2,3-Diphosphoglycerate. (From Miller RD. The oxygen dissociation curve and multiple transfusions of ACD blood. In: Howland WS, Schweizer O, eds. *Management of Patients for Radical Cancer Surgery: Clinical Anesthesia Series.* Vol. 9. Philadelphia: FA Davis; 1972:43.)

Recent animal data suggest that red cells in stored blood can be rejuvenated with solutions of inosine prior to administration, reversing storage lesions and mitigating the potential for organ damage. This could be a promising technique to restore ATP and 2,3-DPG levels, while reducing a recipient's immune response and transfusion-associated organ injury.[46] However, small clinical trials in humans demonstrating clinical benefit are lacking.[47] Larger trials are ongoing.

CLINICAL IMPLICATIONS: DURATION OF BLOOD STORAGE

The fact that blood can be stored for 42 days is a mixed blessing. The obvious advantage is the increased availability of blood, but the clinical evidence regarding safety has not been consistent, reflecting the difficulty of conducting a systematic study of patients in varied clinical settings. For decades, many clinicians have tried to establish a firm relationship between the 2,3-DPG levels associated with stored blood and patient outcome. In 1993, Marik and Sibbald[48] found that the administration of blood that had been stored for more than 15 days decreased intramucosal pH, suggesting that splanchnic ischemia had occurred. In addition, an increased incidence of postoperative pneumonia in cardiac patients has been associated with the use of older blood.[49] Yet prolonged storage of blood was not associated with increased morbidity after cardiac surgery.[50] Purdy and colleagues[51] found that patients who received 17-day-old blood (range, 5-35 days) versus 25-day-old blood (range, 9-36 days) had higher survival rates. Koch and colleagues[52] concluded that giving erythrocytes (PRBCs) older than 14 days was associated with an increased risk for postoperative complications, along with reduced short-term and long-term survival in patients undergoing coronary artery bypass surgery. This article also had an accompanying editorial that concluded, "to the extent possible, newer blood might be used in clinical situations that seem to call for it."[53] In addition, a meta-analysis concluded that older stored blood is associated with an increased risk for death.[54]

However, there is equal data arguing the contrary, and other researchers have not arrived at a clear conclusion and recommended more studies. Weiskopf and associates[55] performed studies in healthy volunteers who were evaluated by a standard computerized neuropsychologic test 2 days and 1 week after acute isovolumic anemia was induced. When correcting the anemia, they concluded that erythrocytes stored for 3 weeks are as efficacious as those stored for 3.5 hours. Spahn[4] wrote an accompanying editorial agreeing with Weiskopf and associates[55] and, furthermore, postulated that 2,3-DPG levels may not be the key factor in determining the delivery of O_2 (i.e., 2,3-DPG levels are reduced in older blood, but the blood still delivers O_2). Cata and associates[56] also concluded that no change in outcome occurred in patients undergoing radical prostatectomy and receiving older blood. Saager and colleagues[57] also found no relationship between duration of blood storage and mortality in nearly 7000 patients undergoing noncardiac surgery.

Since the publication of the eighth edition of this text, several randomized control trials evaluating the influence of the duration of blood storage have been published. In 2016, Heddle and colleagues[58] published results from the INFOMR trial, a large, pragmatic, randomized controlled trial enrolling adult hospitalized patients in six centers from four countries. Patients were randomized to receive either blood that had been stored for the shortest duration (mean duration of storage 13 days) versus blood stored for the longest duration (mean duration of storage 23 days). Only patients with A and O blood types were included as the less common blood types could not achieve an appropriate difference in mean duration of storage. More than 20,000 patients were included in the primary analysis. No significant differences in mortality were noted between the two groups. In prespecified high-risk categories, including patients undergoing cardiovascular surgery, patients admitted to the intensive care unit (ICU), and those with cancer, the results remained the same.

Similarly, the results of the recent RECESS trial published in 2015[59] revealed similar mortality rates among those transfused with blood stored less than 10 days (median storage time 7 days) compared with those transfused with blood stored for more than 21 days (median storage time 28 days). Changes in preoperative to 7 days postoperative Multiple Organ Dysfunction Score (MODS) were similar between the two groups, as well. Finally, two randomized controlled trials in critically ill adults evaluating the age of transfused blood on mortality and other outcomes, such as new bloodstream infections, duration of mechanical ventilation, and the use of renal replacement therapy, failed to demonstrate differences between groups transfused with fresher blood compared with those transfused with older blood.[60,61]

These recent randomized controlled trials demonstrate the safety and noninferiority of "older" versus "younger" blood, but the complete answer may still need further data. First, the measures of outcome may be insufficiently sensitive to detect important and meaningful clinical outcomes. Many studies use mortality as their primary outcome measure. Although this is obviously a critical benchmark, it may not be sensitive enough to detect clinical differences regarding the safe or optimal length of time for the storage of blood. Important adverse clinical outcomes could occur without a change in mortality per se (e.g., duration of hospitalization, cardiovascular events, quality of life, neurocognitive decline). Second, these studies compare moderately young with moderately old blood. Ethical and logistical issues preclude a trial comparing "very" young and "very" old blood or even comparing moderately aged blood to very old blood (e.g., stored for 35-42 days).[62-64] Because the quality of blood decreases with length of storage, increased morbidity with exposure to more aged red cells is physiologically plausible, but the debate regarding the effectiveness of a blood transfusion and its duration of storage continues. More prospective studies are likely required.

Blood Component Therapy: Indications for Transfusion

A major advance in the field of blood banking has been the development of blood component therapy. The basic philosophy is that patients are best treated by administration of the specific fraction of blood that they lack. This concept has presented problems to the surgical team, who often desire the physiologic effects of whole blood.

ALLOGENEIC (HOMOLOGOUS) BLOOD

PRBCs contain the same amount of Hb as whole blood, but much of the plasma has been removed. The Hct value of PRBCs is approximately 60% (Table 49.5). Other than severe hemorrhage, most indications for RBCs can be effectively treated with PRBCs, conserving the plasma and the components for other patients (see Fig. 49.1). Many blood banks have conscientiously followed this principle, and whole blood is not available or only available in trauma centers or by special arrangement.

The administration of PRBCs is facilitated by utilizing crystalloid or colloid as a carrier; however, not all crystalloids are suitable. Solutions containing Ca^{2+} may precipitate clotting. Lactated Ringer solution is not recommended for use as a diluent or carrier for PRBCs because of the Ca^{2+} (Table 49.6), although several experimental studies found lactated Ringer solution and normal saline to be equally acceptable.[65,66] A more important factor may be whether the diluent is hypotonic with respect to plasma. In hypotonic solutions, the RBCs will swell and eventually lyse.

TABLE 49.5 Metabolic Characteristics of Packed Red Blood Cells

Value	Packed Red Blood Cells
Hematocrit (%)	57
pH	6.79
pCO_2 (mm Hg)	79
Bicarbonate (mmol/L)	11
Plasma sodium (mmol/L)	126
Plasma potassium (mmol/L)	20.5
Glucose (mmol/L)	24
Lactic acid (mmol/L)	9.4

From Sumplemann R, Schürholz T, Thorns E, et al. Acid-base, electrolyte and metabolite concentration in packed red blood cells for major transfusion in infants. *Paediatr Anaesth*. 2001;11:169–173.

TABLE 49.6 Compatibility of Blood With Intravenous Solutions

	HEMOLYSIS AT 30 MIN	
Blood to Intravenous Solution (1:1 Ratio)	**Room Temperature**	**37°C**
5% Dextrose in water	1+	4+
Plasmanate*	1+	3+
5% Dextrose in 0.2% saline	0	3+
5% Dextrose in 0.45% saline	0	0
5% Dextrose in 0.9% saline	0	0
0.9% Saline	0	0
Normosol-R, pH 7.4†	0	0
Lactated Ringer solution	0 (clotted)	0 (clotted)

*Cutter Laboratories, Berkeley, CA.
†Abbott Laboratories, Chicago, IL.

Solutions that cause hemolysis are listed in Table 49.6. Recommended solutions compatible with packed erythrocytes are 5% dextrose in 0.45% saline, 5% dextrose in 0.9% saline, 0.9% saline, and Normosol-R with a pH of 7.4.

RBC transfusions are given to increase O_2-carrying capacity. Increasing intravascular volume in the absence of significant anemia is not an indication for blood transfusion because volume can be augmented with administration of intravascular fluids that are not derived from human blood (e.g., crystalloids). As such, a sole Hb value should not be the only basis for a transfusion decision. It should be the overall status of the patient that prompts transfusion therapy (e.g., hemodynamics, organ perfusion and oxygen delivery, and anticipated surgical needs).[67] Even so, the Hb value has become the basis for many transfusion strategies. It is the prime criterion for defining restrictive versus liberal transfusion strategies.

When a patient is hemorrhaging, the goals should be to restore and maintain intravascular volume, cardiac output, and organ perfusion to normal levels. By using crystalloids, colloids, or both to treat hypovolemia, normovolemic dilutional anemia may be created. Increasing cardiac output enhances O_2 delivery to the tissues only to a limited extent. In fact, during normovolemic anemia, Mathru and colleagues[68] found inadequate splanchnic and preportal O_2 delivery and consumption when the Hb level decreased to 5.9 g/dL. Although the current PBM emphasis is on fewer or even avoidance of blood transfusions, clearly an Hb value exists below which a blood transfusion should be given.

The basis for using the Hb or Hct value as the initial consideration for defining transfusion requirements followed a 1988 National Institutes of Health (NIH) Consensus Conference that concluded that otherwise healthy patients with Hb value more than 10 g/dL rarely require perioperative blood transfusions, whereas patients with acute anemia with a Hb value of less than 7 g/dL frequently require blood transfusions.[69] They also recognized that patients with chronic anemia (as in renal failure) might tolerate an Hb concentration of less than 6 to 7 g/dL. Amazingly, despite many studies, publications, and debates, the fundamental guidelines have not changed substantially in the 30 plus years since this conference.

An excellent editorial by LeManach and Syed[70] outlines key questions that should be considered regarding transfusion triggers, including what we need to learn and the role of databases. Of prime importance is identifying the variables that predict the need for erythrocyte transfusion and the approach that can most accurately estimate the impact of transfusions. Many studies use death rate as their main indicator. Although clearly an important indicator, there are additional obvious factors in between the extremes of life and death, including vital signs, key laboratory values, and other indicators used in critical care units. Several groups working with patients in ICUs have attempted to define the point at which blood transfusions should be given by measures of tissue oxygenation and hemodynamics (e.g., increase in O_2 consumption in response to added O_2 content).[71-73] The O_2 extraction ratio has been recommended as an indicator for transfusions;[74] however, this technique requires invasive monitoring, and the results were not dramatic between groups who were or were not transfused. No specific measure can consistently predict when a patient will benefit from a blood transfusion. The ultimate determination of the Hb or Hct value at which blood should be given is a clinical judgment based on many factors, such as cardiovascular status, age, anticipated additional blood loss, arterial oxygenation, mixed venous O_2 tension, cardiac output, and intravascular blood volume (Table 49.7).

ADDITIONAL BLOOD TRANSFUSIONS

To determine whether subsequent units of blood are indicated after the initial administration, the overall condition of the patient and the clinical situation need to be reassessed. The following key components of information to consider include:

1. Measurement and trend of vital signs
2. Measurement of blood loss and assessment of anticipated blood loss
3. Quantitation of intravenous fluids given
4. Determination of Hb concentration
5. Surgical concerns.

TABLE 49.7 American College of Surgeons Classes of Acute Hemorrhage

Factors	Class I	Class II	Class III	Class IV
Blood loss (mL)	750	750-1500	1500-2000	2000 or more
Blood loss (% blood volume)	15	15-30	30-40	40 or more
Pulse (beats/min)	100	100	120	140 or higher
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mm Hg)	Normal or increased	Decreased	Decreased	Decreased
Capillary refill test	Normal	Positive	Positive	Positive
Respirations per minute	14-20	20-30	30-40	35
Urine output (mL/h)	30	20-30	5-10	Negligible
Central nervous system: mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement (3-1 rule)	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

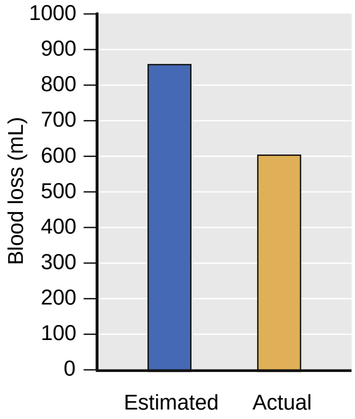

Fig. 49.3 Discrepancy between estimated and actual blood loss. (From Stovener J. Anesthesiologists vastly overstate bleeding. *Anesthesiol News*, May 14, 2012.)

Measurement of Blood Loss

Measuring blood loss is obviously important when assessing the need for both the initial and subsequent blood transfusions (see Table 49.7). A standard approach includes a combination of visualization and gravimetric measurements based on weight differences between dry and blood-soaked gauze pads. A study in patients undergoing spine surgery found that anesthesiologists tended to overestimate blood loss by as much as 40% (Fig. 49.3). On the other hand, optical scanners tended to underestimate blood loss compared with the standard gravimetric calculations.[75] The accuracy of measurements is not uniformly consistent and no "gold standard" for blood loss quantification exists.

Predicting surgical blood loss is also an important component to intraoperative transfusion medicine. As part of the WHO preoperative guidelines to improve the safety of patients undergoing surgery, the anesthesiologist must consider the possibility of a large-volume blood loss prior to the induction of anesthesia.[76] In a prospective trial evaluating both surgeons' and anesthesiologists' ability to predict the estimated blood loss prior to incision, members of both these medical professions underestimated the blood loss by greater than 500 mL in 10% of intermediate or major surgeries, which potentially placed those patients at risk for being without adequate intravenous access or appropriate resuscitative volume.[77]

Determination of Hemoglobin Concentration

While transfusion decisions depend on many clinical factors, the blood Hb value is an important measurement that is fraught with confounding variables. With regard to measurement of blood loss, clinical investigators at Duke University emphasized that "interpretation of intermittent measurements of Hb levels is often complicated by fluid shifts, intravenous volume infusions, and actual transfusions,"[78] yet these values are critical to transfusion decisions.

Continuous blood Hb monitoring has become available on a noninvasive basis using spectrophotometric finger technology (Masimo SpHb, Masimo, Irvine, CA). Numerous studies have been performed in a variety of clinical situations with emphasis on assessment of blood loss and/or the need for transfusions. Although measurements are relatively accurate (i.e., SpHb correlate within 1.0-1.5 g/dL with laboratory Hb measurements), the appearance of inaccurate values is not uncommon.[79,80] SpHb appears to perform worse in patients with moderately to severely low Hb levels or in patients being actively resuscitated.[81,82]

Accuracy also depends on finger blood flow and temperature. The monitor displays a value for perfusion index (PI), which can be helpful in assessing the accuracy of the SpHb value. The accuracy of SpHb can be improved with a PI greater than 4% to 5%. A bupivacaine digital nerve block decreases the number of inaccurate values and increases the number of accurate values for several hours.[83,84] Although not specifically studied, warming the finger should also increase the PI and, therefore, the accuracy of SpHb.

SpHb monitoring can still be valuable even though its accuracy is not consistent. Observation of the trend is often recommended to help clinicians detect a changing Hb level when it is suspected to be stable. For example, Giraud and colleagues[85] concluded that SpHb is less invasive and less accurate than other measurements but provides valuable data on a continuous basis. They then concluded that none of the results would have led to transfusion errors as identified by the American Society of Anesthesiologists (ASA) Task Force on Perioperative Blood Transfusion and Adjuvant Therapies' practice guidelines. If the SpHb value suddenly changes 1 or 2 g/dL, the reasons for this change should be explored, even if the absolute value is satisfactory. For example, if the SpHb reading is 11 g/dL, but rapidly decreases to 9.5 g/dL, the clinical situation needs to be reassessed. Although an attractive concept and possibly accurate, more definitive studies are necessary.[86] SpHb could become very valuable with transfusion decision making in the future.[87]

Invasive point-of-care testing, such as HemoCue (HCue; Hemocue America, Brea, CA), provides a quick and efficient method to accurately determine Hb value. This point-of-care test allows for the determination of Hb levels at the bedside in less than 5 minutes. If the person performing the test is properly trained, HCue measurements are extremely accurate.[80,85] Several other point-of-care Hb tests exist, including RapidLab (Siemens, Malvern, PA) and I-Stat (Abbot Inc, Princeton, NJ). Comparative testing of these three modalities demonstrates favorable intertest reliability.[88]

Preoperative Anemia

Preoperative anemia (i.e., low Hb value in women <12 g/dL; in men <13 g/dL) is a common comorbidity among patients undergoing major surgery with an incidence up to 40% and is an independent risk factor for increased perioperative mortality,[89] and postoperative acute kidney injury (AKI).[90] In patients with a moderate to high risk of significant blood loss (defined as >500 mL), the Hb value ideally should be obtained 3 to 8 weeks prior to surgery.[91] This provides sufficient time for the patient to undergo iron therapy or to correct nutritional deficiencies. Erythropoiesis-stimulating agents, especially intravenously administrated iron therapy, may be beneficial for treatment of preoperative anemia. The concept of treating anemia preoperatively as a means to decrease the need for intraoperative transfusions is widely accepted. For example, intravascular iron therapy in patients undergoing abdominal surgery significantly increased preoperative Hb levels, reduced the need for transfusion, and shortened hospital length of stay.[92] PREVENTT, a large phase III randomized controlled trial investigating preoperative intravenous iron therapy, is ongoing to further characterize this intervention. Oral therapy, if given with sufficient time preoperatively and tolerated by the patient, may be just as effective at correcting the anemia as intravenous therapy.[93]

Erythropoiesis-stimulating agents (ESAs), such as darbepoetin alfa, act by stimulating red cell progenitor cells in the bone marrow and inducing erythropoiesis. They are frequently prescribed for patients with anemia who have end-stage renal disease or who are undergoing chemotherapy treatment to increase their Hb levels and reduce the incidence of transfusion. The evidence has been mixed on the utility and safety of ESAs as a means to increase Hb levels and decrease transfusions in various perioperative patient populations. This may be a result of the heterogeneity of study protocols. A more recent randomized controlled trial in patients undergoing cardiac surgery found a decreased incidence of transfusion in patients with preoperative anemia who were treated with a single dose of erythropoietin administered 2 days prior to surgery.[94] Although no difference in adverse events was noted, the study was underpowered, leaving the question of safety due to the association of ESAs with hypertension and thrombotic events unanswered.[95]

If limited preoperative time is available, Karkouti and associates[96] suggested that prophylactic erythrocyte transfusion should be used to reduce perioperative anemia. This suggestion met with controversy, and many editorials and letters to the editor were written supporting[97] and condemning[98] such an approach. Recent retrospective data suggest that preoperative transfusion, even in severely anemic patients, offers no benefit and may be an independent predictor of complications in some patients.[99]

Liberal Versus Restrictive Transfusion Strategy

The terminology of liberal versus restrictive has become completely indoctrinated into the transfusion therapy vocabulary. Several medical and surgical organizations have provided documents regarding their own definition of liberal and restrictive approaches. Some of these organizations include the American Association of Blood Banks,[100] International Conference on Transfusion Outcomes Group,[6] and Surgical Hip Fracture Repair (FOCUS).[101] In fact, many of these studies were supported by the NIH, which is an indication of how important this topic is for patient care.

Liberal versus restrictive transfusion strategy is based on the Hb value when a transfusion decision is made. A restrictive policy is the administration of blood transfusion when the Hb value is 7 to 8 g/dL or less. In contrast, a liberal policy is the administration of blood transfusion when the Hb value is 9 to 10 g/dL or greater. Many studies have been performed in multiple clinical situations, with varying patient conditions and acuity. The most recent randomized controlled studies continue to show no benefit to a liberal strategy compared with a restrictive strategy. One conclusion is that if no clinical advantages are associated with the liberal transfusion policy, perhaps the restrictive approach should be used. Certainly, fewer transfusion reactions would be expected with the restrictive approach.[101]

How liberal should the transfusion trigger be in critically ill patients? Some critical care physicians have suggested that administration of blood transfusions is related to the incidence of ventilator-assisted pneumonia[102] and nosocomial infections.[103] Although this possibility cannot be excluded, these are complicated outcomes with many confounding variables. Despite the difficulty with identifying a specific transfusion trigger, Ely and Bernard[104] have generally confirmed the conclusions discussed earlier: better outcomes have not consistently occurred with liberal transfusion triggers (i.e., 9.0 to 10.0 g/dL).[105,106] Subsequent editorials have leaned toward a lower transfusion trigger even for critically ill patients.[107,108]

Recent data from prospective, randomized controlled trials in high-risk cardiac surgery patients and critically ill patients with septic shock continue to show the noninferiority of restrictive transfusion thresholds.[109,110] In addition, a meta-analysis of randomized trials of liberal versus restrictive transfusion approaches concluded, “restrictive strategies may decrease the incidence of healthcare-associated infections.”[111]

Perhaps a one-value, one-size-fits-all approach to a liberal versus restrictive transfusion strategy is too simplistic of an approach for transfusion decision making. In an editorial, Beattie and Wijeysundera[67] advocated for a more context-specific approach to appropriate transfusion triggers. That is, the transfusion trigger for an otherwise healthy young adult patient should be different than that for an elderly patient with significant cardiovascular comorbidities. The American College of Surgeons attempted to categorize patient characteristics and blood loss as a basis for transfusion decisions (see Table 49.7). Small aggregate data support this theory of customized transfusion thresholds, but the results have yet to be proven in a prospective, randomized trial.[112] Hb values are important, but the overall condition of the patient may be of prime importance.

In addition to a dichotomized one-size-fits-all approach, the liberal versus restrictive strategy associated with PBM has some additional limitations. This strategy primarily addresses the indications for administering an initial unit of blood.[113] Most of this strategy is directed toward anemia in stable patients who are not actively bleeding. It does not describe what the indications for administration of subsequent units of blood should be. The need for repetitive transfusions in a bleeding patient is not addressed in the liberal versus restrictive discussion. Yet it is a very important topic for anesthesia providers. Patients with active bleeding, especially those with cardiovascular disease, should probably be subjected to a more liberal transfusion strategy.[114]

General Conclusions

The emphasis on Hb levels for transfusion decisions needs some caution. There can be variability from one patient to another regarding the need for increased O_2-carrying capacity via blood transfusions. Also, an individual patient's Hb level may vary markedly in the perioperative period independent of and in addition to transfusions of RBCs. During acute bleeding, Hb values are only slightly decreased initially because the intravascular volume has not been repleted and the Hb level has not been diluted.[114] The development of more sensitive indicators of tissue oxygenation (e.g., intramucosal pH) may provide indicators for transfusion in the future. As concluded by Weiskopf,[115] "we merely await advances in technology that will enable us to measure directly the value of concern and thereby free us from arguments over which surrogate (e.g., hemoglobin) to measure and what value indicates the need for augmented oxygen delivery." Although Weiskopf wrote this opinion in 1998, surrogate indicators are still used for transfusion decisions today.

In the presence of incomplete data, the ASA's 2015 updated practice guidelines offer these recommendations:[116]

1. Transfusion is rarely indicated when the Hb concentration is more than 10 g/dL and is almost always indicated when it is less than 6 g/dL, especially when the anemia is acute.
2. A restrictive transfusion strategy (Hb <8 g/dL) should be employed to reduce the patient's transfusion requirements and decrease the potential harmful effects of transfusions.
3. Multimodal protocols and algorithms should be employed to reduce intraoperative blood loss and transfusion requirements. These pathways include point-of-care testing to direct care.
4. The use of a single Hb trigger for all patients and other approaches that fail to consider all important physiologic and surgical factors affecting oxygenation is not recommended.
5. When appropriate, intraoperative and postoperative blood recovery, acute normovolemic hemodilution (ANH), and measures to decrease blood loss (i.e., deliberate hypotension and pharmacologic drugs) may be beneficial.

PLATELET CONCENTRATES

Platelet concentrates are obtained either as pooled concentrates from 4 to 6 whole-blood donations or as apheresis concentrates obtained from one donor.[117] If platelets are stored at room temperature, they can be used up to 7 days after collection with constant and gentle agitation. Bacterial contamination, mainly from platelet concentrates, is the third leading cause of transfusion-related deaths (Table 49.8), although the incident rate has steadily declined over the last 15 years.[118] In a report of 10 contaminated platelet transfusions between 1982 and 1985, half were platelets stored for 5 days or more. A prospective analysis from 1987 to 1990 resulted in seven cases of sepsis in patients receiving platelets for thrombocytopenia secondary to bone marrow failure.[119] Because the use of multidonor platelet products stored for 5 days results in an incidence of sepsis five times higher than use of those stored for 4 days, shorter storage times are being emphasized. In studies that actively survey transfused platelets,[120] a rate of bacterial contamination has been identified of approximately 1 per 2500 units (Table 49.9). Twenty-five percent of the patients exposed to contaminated platelet products developed a septic transfusion reaction, although these cases were only identified by active surveillance. Prior to this study, septic transfusion reactions associated with platelet transfusions were reported at a rate of 1 per 100,000 transfused platelets, suggesting this is likely an underreported event.[121]

TABLE 49.8 Transfusion-Related Fatalities in the United States, 2012 Through 2016

Complication	FY 2012-2015 (Number)	FY 2012-2015 (Percent)	FY 2016 (Number)	FY 2016 (Percent)
Anaphylaxis	6	4	5	12
Contamination	14	10	5	12
HTR (ABO)	10	7	4	9
HTR (non-ABO)	18	13	1	2
Hypotensive Reaction	2	1	1	2
TACO	37	26	19	44
TRALI	56	39	8	19

TABLE 49.9 History of Platelet Concentrates Shelf Life in Relationship to Key Events

Year	Shelf Life	Practical Shelf Life*
1984-1986	7 days	6-7 days†
1986-1999	5 days	3 days‡
1999-2004	5 days	3 days§
2004-present	5 days	2.5-3 days

*Days that platelet concentrates are actually available to clinicians.

†Reports of bacterial contamination.

‡Nucleic acid technology testing, centralized blood donor testing.

§Bacterial detection implemented.

At present, platelet concentrates are routinely tested for bacteria and are the only blood product stored at room temperature.[122] For any patient who develops a fever within 6 hours after receiving platelets, sepsis from platelets should be considered.

Indications for the use of platelets are somewhat difficult to define. The most recent guidelines published in 2015 by the ASA Task Force on Perioperative Blood Management[116] provide the following recommendations regarding management for platelet transfusions:

1. Monitor platelet count, except in situations of massive transfusion.
2. Monitor platelet function, if available.
3. Consider use of desmopressin in patients with excessive bleeding or suspected platelet dysfunction.
4. Platelet transfusion may be indicated despite an adequate platelet count if there is known or suspected platelet dysfunction (e.g., cardiopulmonary bypass, bleeding, recent use of antiplatelet therapy, congenital platelet dysfunction).
5. Prophylactic platelet transfusion is rarely indicated in surgical or obstetric patients when the platelet count is greater than 100×10^9/L and is usually indicated when the platelet count is less than 50×10^9/L. The determination of whether patients with intermediate platelet counts ($50\text{-}100 \times 10^9$/L) require therapy should be based on the patient's risk for bleeding.

Many institutions have strict thresholds targeted to the patient's condition that outline the minimum platelet count needed for the categories of (1) prophylaxis, (2) periprocedural (based on type of procedure), and (3) active bleeding. In the first category, a required platelet count may be 10×10^9/L in patients receiving chemotherapy.[123] In the second category, patients undergoing bone marrow biopsy or lumbar puncture should have platelet counts between 20 and 30×10^9/L. For neurosurgery, a platelet count of 100×10^9/L may be targeted. Such thresholds are often guided by professional societies. The American Society of Regional Anesthesia and Pain Medicine guidelines also include recommendations in the setting of therapy that may alter platelet function.[124] A clinician's institution will likely have precise platelet recommendations for most procedures.

Patients with severe thrombocytopenia ($<20 \times 10^9$/L) and clinical signs of bleeding usually require platelet transfusion. However, patients may have very low platelet counts (much lower than 20×10^9/L) and not have clinical bleeding. These patients probably do not need platelet transfusions (Table 49.10). The recent PATCH trial evaluated patients receiving antiplatelet therapy who presented with intracerebral hemorrhage (ICH).[125] Such patients often receive platelet transfusions due to concern about the irreversible inhibition of platelet function and the high risk of morbidity and mortality associated with ICH. Study participants were excluded if their Glasgow Coma Scale score was less than 8 or if their treatment plan included expected surgical intervention within the first 24 hours of presentation. Platelet transfusion increased the risk of death or dependence at 3 months and the risk of a serious adverse event during the hospital stay compared with standard medical therapy without transfusion. Although this study excluded patients who were deemed surgical candidates at presentation, even in this high-risk patient population, platelet transfusions are not indicated unless there is active bleeding.

TABLE 49.10 Correlation Between Platelet Count and Incidence of Bleeding

Platelet Count (cells/mm^3)	Total No. Patients	No. Patients With Bleeding
>100,000	21	0
75,000-100,000	14	3
50,000-75,000	11	7
<50,000	5	5

Data from Miller RD, Robbins TO, Tong MJ, et al. Coagulation defects associated with massive blood transfusions. *Ann Surg*. 1971;174:794.

When possible, ABO-compatible platelets should be used. The need to use them, however, is not well documented, and specific testing is difficult. Aggregation cannot be used for matching, because platelets cause clumping. The platelet membrane has immunoglobulins, and any additional deposit of recipient antibodies is difficult to detect. Despite the fact that platelets can be destroyed by antibodies directed against class I human leukocyte antigen (HLA) proteins on their membranes and by antibodies against ABO antigens, platelets will continue to be chosen without regard to antigen systems for the majority of patients.[126] ABO-incompatible platelets produce very adequate hemostasis.

The effectiveness of platelet transfusions is difficult to monitor. Under ideal circumstances, one platelet concentrate usually produces an increase of approximately 7 to 10×10^9/L at 1 hour after transfusion in the 70-kg adult. Ten units of platelet concentrates are required to increase the platelet count by 100×10^9/L. However, many factors, including splenomegaly, previous sensitization, fever, sepsis, and active bleeding, may lead to decreased survival and decreased recovery of transfused platelets.

Other various different types of platelet concentrates have been proposed, including leukocyte-depleted platelets and ultraviolet–irradiated platelets. The use of these products is reviewed by Kruskall.[127]

FRESH FROZEN PLASMA

FFP is the most frequently used plasma product. It is processed shortly after donation, generally frozen within 8 hours or 24 hours (PF24). It contains all the plasma proteins, particularly factors V and VIII, which gradually decline during the storage of blood. PF24 is comparable to FFP, except for a slight reduction in factor V and approximately 25% decrease in factor VIII.[128,129] Thawed plasma is stored at 1 °C to 6 °C for up to 5 days. The use of FFP carries with it the same inherent risks that are observed with the use of any blood product, such as sensitization to foreign proteins.

Although FFP is a reliable solution for intravascular volume replacement in cases of acute blood loss, alternative therapies are equally satisfactory and considerably safer. The risks of FFP administration include TRALI, TACO, and allergic or anaphylactic reactions.

In 2015 the ASA Task Force recommended the following guidelines regarding the administration of FFP:

1. Prior to the administration of FFP, coagulation studies should be obtained when feasible.
2. For the correction of coagulopathy when the international normalized ratio (INR) is greater than 2, in the absence of heparin.
3. For the correction of coagulopathy due to coagulation deficiencies in patients transfused with more than one blood volume (approximately 70 mL/kg) when coagulation studies cannot be easily or quickly obtained.
4. Replacement of known coagulation factor deficiencies with associated bleeding, disseminated intravascular coagulation (DIC), or both, when specific components are not available.
5. Reversal of warfarin anticoagulation when severe bleeding is present and prothrombin complex concentrations are not available.

FFP or plasma is often given to critical care patients before insertion of an intravascular catheter. Hall and associates[130] studied 1923 patients admitted to 29 ICUs in the United Kingdom who underwent intravascular catheterization. They compared patients who did and did not receive FFP. Chronic liver disease and more abnormal coagulation tests increased the frequency of patients receiving FFP, but the severity of the prothrombin time (PT) alone was not a factor. Whether prophylactic FFP should be given in this situation is not well defined. In 2015, Muller and associates[131] published results from a randomized, open-label trial of prophylactic FFP use prior to an invasive procedure in critically ill patients with an INR of 1.5 to 3. The trial ended before reaching target enrollment, because of slow recruitment. The occurrence of bleeding did not differ between the two groups, but the trial may not have had enough power to distinguish a statistical significance between groups. Also, an INR reduction below 1.5 only occurred in 54% of patients in the intervention group.

In an effort to “expedite” the availability of plasma for patients who require massive transfusions, some trauma centers keep thawed plasma readily available. In one study, patients with severe trauma who had already received 1 unit of RBCs and plasma were then divided into two groups, one of which immediately received 4 units of thawed plasma. The patients who received the plasma had a reduction in overall blood product use and 30-day mortality.[132] More recently, Sperry and colleagues[133] randomized prehospital injured patients in flight transport who were at risk for hemorrhage to standard of care versus empiric administration of 2 units FFP. By 3 hours, Kaplan-Meier curves revealed early separation of the two groups, favoring empiric administration of FFP in the prehospital setting that persisted until their prespecified end point of 30 days following randomization.

CRYOPRECIPITATE

Cryoprecipitate is prepared when FFP is thawed, and the precipitate is reconstituted. The product contains factor VIII:C (i.e., procoagulant activity), factor VIII:vWF (i.e., von Willebrand factor), fibrinogen, factor XIII, and fibronectin, which is a glycoprotein that may play a role in reticuloendothelial clearance of foreign particles and bacteria from the blood. All other plasma proteins are present in only trace amounts in cryoprecipitate.

Cryoprecipitate is frequently administered as ABO compatible; however, this probably is not very important because the concentration of antibodies in cryoprecipitate is extremely low. Cryoprecipitate may contain RBC fragments, and cryoprecipitate prepared from Rh-positive donors can possibly sensitize Rh-negative recipients to the Rh antigen. Cryoprecipitate should be administered through a filter and as rapidly as possible. The rate of administration should be at least 200 mL/h, and the infusion should be completed within 6 hours of thawing.

According to the 2015 ASA Task Force on Perioperative Blood Management,[116] transfusion of cryoprecipitate is rarely indicated when the fibrinogen levels are greater than 150 mg/dL in nonobstetric patients. The following indications were provided regarding the administration of cryoprecipitate:

1. When testing of fibrinogen activity reveals evidence for fibrinolysis
2. When fibrinogen concentrations are less than 80 to 100 mg/dL in patients experiencing excessive bleeding
3. Obstetrical patients who are experiencing excessive bleeding despite a measured fibrinogen concentration greater than 150 mg/dL
4. In patients undergoing massive transfusion when the timely assessment of fibrinogen concentrations cannot be determined
5. In patients with congenital fibrinogen deficiencies and when possible, in consultation with the patient’s hematologist
6. In bleeding patients with von Willebrand disease types 1 and 2A who fail to respond to desmopressin or vWF/FVIII concentrates (or if not available)
7. In bleeding patients with von Willebrand disease types 2B, 2M, 2N, and 3 who fail to respond to vWF/FVIII concentrates (or if concentrates are not available)

Fibrin glue may be used by surgeons to create local hemostasis. It is prepared in a manner similar to that of cryoprecipitate. With added thrombin, it is applied locally to the surgical site. The efficacy of this product has been difficult to demonstrate in clinical trials.

MASSIVE TRANSFUSION AND TRANSFUSION RATIOS

The transition from administration of whole blood to component therapy in the 1970s created new challenges in transfusion medicine, especially in patients undergoing trauma or any type of surgery associated with significant blood loss. FFP was not usually required as a separate component with the administration of whole blood, and significant thrombocytopenia usually occurred only after 15 to 20 units of blood.[5] With the change from whole blood to PRBCs, the incidence of coagulopathies increased, especially in units responsible for trauma patients. Rather than basing transfusion decisions on clinical judgment or laboratory tests, the concept of developing ratios of FFP and/or platelet concentrates with PRBCs evolved. For example, a 1:1:1 ratio would be transfusion of 1 unit of plasma, and one-sixth unit of platelets to 1 unit of RBCs. A 1:1:2 ratio would be transfusion of 1 unit of plasma, and one-sixth unit of platelets to every 2 units of RBCs. The convention of one-sixth unit of platelets results from the common allocation of platelet products in 1 unit (apheresis) from a single donor or 1 pool (pooled) from six donors in a "six pack." In review of the literature, ratios may be expressed as plasma/platelets/RBCs or RBCs/plasma/platelets.

Holcomb and associates[134] concluded that increased platelet ratios were associated with improved survival after massive blood transfusions. Subsequently, Kornblith and associates[135] concluded that the laboratory clotting profile of 1:1:1 plasma/platelets/RBC was significantly more hemostatic when examining activity of factors II, V, VII, VIII, IX, and X; antithrombin III, as well as protein C and higher fibrinogen levels when compared with a 1:1:2 ratio. Results of the Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study supported this idea. With data from 10 U.S. level-I trauma centers, the conclusion of the study[136] was that higher plasma and platelet ratios early in resuscitation were associated with decreased mortality in patients who received transfusions of at least 3 units of blood products during the first 24 hours after admission.[136] Among survivors at 24 hours, the subsequent risk for death by day 30 was not associated with plasma or platelet ratios. When comparing groups of patients with similar Injury Severity Scores, only a survival benefit was seen in ratios with high plasma to RBC resuscitation. However, no additional morbidity benefit of 1:1 over 1:2 ratios was identified.[137]

More recently in the randomized control trial Pragmatic Randomized Optimal Platelet and Plasma Ratios (PROPPR) study, Holcomb and associates[138] found that among patients with severe trauma and major bleeding, early administration of plasma, platelets, and red blood cells in a 1:1:1 ratio versus a 1:1:2 ratio did not result in significant differences in mortality at 24 hours or at 30 days.

These aggressive uses of FFP, platelets, and other blood products have only been shown to be beneficial in response to coagulopathies from massive blood transfusions. Aggressive plasma administration to other transfused patients was associated with an increased rate of serious complications, including acute respiratory distress syndrome (ARDS) and organ dysfunction.[126] A retrospective study showed that a higher FFP-PRBC ratio was associated with the need for advanced interventional procedures in patients with postpartum hemorrhage.[139]

Synthetic Oxygen-Carrying Substances

HB-BASED OXYGEN CARRIERS

Various other substances that carry or facilitate the transport of O_2 have been made. Oxygen therapeutics are labeled as Hb-based O_2 carriers (HBOCs). HBOCs have advantages over human blood of not requiring type and crossmatch and not transmitting infectious viruses, typical characteristics of most synthetic blood products (Table 49.11).

Two approaches have dominated attempts to develop synthetic blood. The first approach uses linear binding kinetics, unlike the nonlinear binding of Hb. The most notable is the perfluorochemical emulsion called Fluosol-DA. Fluosol-DA was initially approved by the FDA for perfusion of ischemic tissues in the setting of percutaneous coronary intervention.[140] However, it had little use because it carried O_2 only when the PaO_2 was more than 300 mm Hg.[141] Fluosol was withdrawn from the market in 1994. Another perfluoro compound, perfluorooctyl bromide, carries three to four times more O_2, has a longer half-life, and presumably fewer problems than are associated with Fluosol-DA, but it is not available on the market.[142]

TABLE 49.11 Comparison of General Synthetic Blood With Allogeneic Blood

Parameter	Synthetic	Allogeneic
Oxygen delivery	Rapid and consistent	Dependent on 2,3-DPG
Risk for disease transmission	None	See Table 49.2
Storage	Room temperature	Refrigeration
	Stable efficacy	Loss of efficacy
Shelf life	1-3 year	42 days
Preparation	Ready to use	Crossmatch
Compatibility	Universal	Type specific
Duration of action	1-3 days	60-90 days

2,3-DPG, 2,3-Diphosphoglycerate.

Most HBOCs modify the Hb molecule from humans, animals, or recombinant technology. Original efforts required Hb to be stroma free to prevent nephrotoxicity. The stroma-free Hb needed to be modified to have a favorable O_2 affinity (i.e., decreased O_2 affinity/right shift in the O_2 dissociation curve) and to extend its relatively short intravascular half-life. A variety of approaches have been used, including crosslinking, pyridoxylation and polymerization, and conjugation and encapsulation to accomplish this. Stroma-free Hb causes severe arteriolar vasoconstriction of microvascular structures from NO scavenging, which is not beneficial for organ perfusion. A human recombinant hemoglobin (rHb 1.1) was made in *Escherichia coli* and functions as normal Hb in terms of O_2-carrying capacity, but it, too, was plagued by microvascular vasoconstriction. Although a subsequent iteration, rHbg 2.0, minimized NO scavenging and caused little arteriolar vasoconstriction when compared with rHb 1.1 and diaspirin crosslinked Hb,[143,144] vasoconstriction may still prove to be their ultimate downfall.

Most clinical trials have shown increased use of allogeneic blood transfusions;[145] however, the outcome of the HBOCs have been similar: failure in clinical trials due to increased adverse events. Natanson and colleagues[146] performed a cumulative meta-analysis on 16 trials involving 5 different products and 3711 patients. They concluded that there was a significant increased risk for myocardial infarction and death when HBOCs were given, an outcome that was found among all the technologies (e.g., cross-linked, polymerized, or conjugated). An accompanying editorial concluded that a 30% increased risk for death and a threefold increase in the risk for myocardial infarction should preclude any additional studies.[147]

Several HBOCs are available clinically under the FDA's Expanded Access (compassionate use) program. HBOC-201 hemoglobin glutamer-250 (bovine), Hemopure (Biopure Corporation) is developed from ultrapurified bovine RBCs that have been glutaraldehyde polymerized. It has a higher P_{50} (i.e., 43 instead of 26 mm Hg), which means that it may deliver O_2 to the tissues at least as well, if not better, than human RBCs.[148] A recent case series reported three cases of HBOC–201, under the FDA's Expanded Access to patients in severe sickle cell crisis (SCC) with multiorgan failure, who refused RBCs (Jehovah's Witnesses) or for whom compatible RBCs were not available.[149] A recent case report described use of bovine pegylated carboxyhemoglobin (Sanguinate) in a Jehovah's Witness with a lymphoproliferative disorder, gastrointestinal bleeding, and resultant severe anemia who was bridged to hemostatic interventions.[150] For now, HBOCs are likely to be reserved for situations in which RBC transfusion is not an option or as a bridge to stabilizing therapy.

Autologous Blood

Autologous blood transfusion constitutes three distinct procedures (1) preoperative autologous donation (PAD), (2) acute normovolemic hemodilution (ANH), and (3) intraoperative and postoperative blood salvage. Although the advantages and disadvantages vary with each technique, autologous transfusion aims to decrease the incidence and severity of complications associated with allogenic transfusions and conserve the supply of banked blood. Autologous blood may also be an acceptable solution in patients with rare blood phenotypes or alloantibodies.[151]

PREOPERATIVE AUTOLOGOUS DONATION

It is assumed that preoperative autologous blood transfusion is safer than allogeneic blood, mainly because of the decreased risk for transfusion-transmissible infections, such as HIV and hepatitis C. However, as blood safety has improved with a marked decrease in infectivity from allogeneic blood, the difference in safety compared with autologous blood is much less. Not surprisingly, the proportion of autologous blood collected has significantly decreased since the peak in the mid-1990s.[152]

To be eligible, the AABB requires that most donor's Hb be no less than 11 g/dL prior to donation. Repeated donations should be separated by a week with 72 hours between the last donation and the time of surgery. The latter recommendation is to ensure restoration of intravascular volume and appropriate testing and preparation of the donated blood.[153] At 72 hours postdonation, while intravascular volume may be restored, red cell mass is not. According to the Hemoglobin and Iron Recovery Study (HEIRS), recovery of 80% red cell mass varies from 25 to more than 168 days.[154] On average, for those who undergo PAD, Hb is 1.1 g/dL less than those who do not donate preoperatively. In a meta-analysis incorporating data from multiple surgical patient populations, while PAD decreased the absolute risk of receiving allogenic blood by 44%, the risk of receiving a transfusion from any source (i.e., allogenic or PAD), increased by 24%, which questions the procedure's use as a transfusion-sparing practice.[155]

BOX 49.2 Contradictions to Participation in Autologous Blood Donation Programs

1. Evidence of infection and risk of bacteremia
2. Scheduled surgery to correct aortic stenosis
3. Unstable angina
4. Active seizure disorder
5. Myocardial infarction or cerebrovascular accident within 6 months of donation
6. High-grade left main coronary artery disease
7. Cyanotic heart disease
8. Uncontrolled hypertension

Donation itself is not without risk. In a study of American Red Cross donors, PAD was associated with nearly 12 times the postdonation hospitalization rate as allogenic donors.[156] The criteria for autologous donation are less stringent than those for allogenic donors, as historically 15% of autologous donors do not meet safety criteria for allogenic donation.[157] As such, certain patient populations are poor candidates for PAD because of their underlying comorbidities. These populations include patients with severe cardiopulmonary disease (e.g., severe aortic stenosis, recent myocardial infarction, or cerebrovascular event) and those with bacteremia (Box 49.2).

ACUTE NORMOVOLEMIC HEMODILUTION

ANH is a procedure initiated before the start of significant blood loss, by which the anesthesiologist removes whole blood from a patient while simultaneously restoring intravascular volume with either crystalloid (3 mL/1 mL of blood removed) or colloid (1 mL/1 mL of blood removed) solutions to maintain adequate hemodynamics. Blood is collected in standard blood bags containing citrate anticoagulant and maintained at room temperature in the operating room for up to 8 hours or at 4°C for 24 hours. Bleeding that occurs following ANH sheds a lower percentage of RBCs per unit of total blood volume lost, constituting the presumed major benefit of this procedure.[158]

When major bleeding has stopped or when clinically appropriate, the sequestered blood is then reinfused into the patient in the reverse order of collection because the first unit collected has the highest concentration of coagulation factors and platelets and the highest Hb level.[159] Although some providers advocate that stored blood be gently agitated to preserve platelet function, most practitioners do not do this, and no formal recommendations exist requiring this procedure. Reassuringly, no differences in thromboelastography (TEG) measurements have been noted between samples agitated during storage compared with those left stationary.[160]

The amount of blood saved by ANH is both of a function of the postdilutional Hb achieved and the amount of blood volume lost intraoperatively, the latter hopefully occurring after the blood salvage. Patients undergoing minimal ANH—less than 15% of a patient's blood volume—would only save 100 mL of RBCs, equaling 0.5 units of PRBCs. However, increasing the ANH to target postdilutional Hct of 28% in the setting of 2600 mL blood loss resulted in savings of 215 mL of RBC compared with blood loss without prior hemodilution (Fig. 49.4).[161]

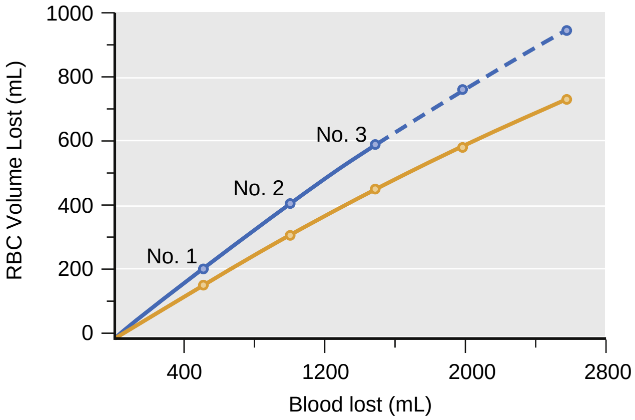

Fig. 49.4 The relationship between whole blood volume *(mL)* lost (abscissa) and red blood cell *(RBC)* volume lost *(ordinate)* in a 100-kg patient undergoing hemodilution: RBC volume lost with 2800 mL whole blood intraoperatively after hemodilution of 1500 mL whole blood *(solid blue line)*; RBC volume lost with 2800 mL whole blood lost during hemodilution at each of three 500 mL volumes *(solid orange line)*; cumulative RBC volume lost intraoperatively, derived for 2800 mL whole blood lost if hemodilution had not been performed *(blue dashed line)*. A net of 215 mL reduction in RBC volume lost with hemodilution is illustrated by the divergence of the two curves. (From Goodnough LT, Grishaber JE, Monk TG, et al. Acute preoperative hemodilution in patients undergoing radical prostatectomy: a case study analysis of efficacy. *Anesth Analg*. 1994;78:932–937, with permission.)

Although larger volumes of hemodilution provide the largest benefit in terms of RBC mass saved and allogenic transfusions avoided,[162] retrospective data suggest that even mild ANH may help to improve outcomes.[163] Prospective, randomized trials demonstrate ANH as a means to decrease transfusion requirements in multiple types of surgeries, including hip replacement,[164] hepatic resection,[165] and vascular surgery.[166] A recent meta-analysis evaluated 29 randomized controlled trials involving 1252 patients undergoing ANH (and 1187 controls) during cardiac surgery.[167] They found patients who underwent ANH were transfused less frequently than those in the control groups, receiving on average three-fourths fewer allogenic blood units than those in the control groups. Not surprisingly, patients undergoing ANH experienced less postoperative blood cell mass loss with a mean loss of 388 mL in the ANH groups and 450 mL in the control groups. Another meta-analysis demonstrated similar findings in a broader patient population that included multiple surgical specialties, but the findings were criticized due to the heterogeneity of the studies included and the potential for publication bias, which would likely overestimate any true benefit.[168] ANH has also been shown to decrease the need for other component therapy, because the removal of whole blood also removes and stores platelets and plasma.[162] In cardiac surgery specifically, ANH may protect the sequestered blood from the effects of cardiopulmonary bypass and the platelet dysfunction that occurs.[169]

Decisions regarding the use of ANH should be made with consideration given to the patient's vital signs, Hct, blood volume, and the estimation of surgical blood loss and risk of transfusion (Box 49.3). ANH is not without potential risk. A recent study in porcine animal models demonstrated significant adverse effects of ANH transfusions particularly in the adult compared with infant animal models. These effects included the development of bronchoconstriction and acute lung injury as a result of extravasation of fluid and deterioration of cardiopulmonary hemodynamics.[170] Similarly, in dog models, ANH to a Hct of 30% demonstrated decreased oxygen delivery to the kidneys with preserved delivery to other organs, including the heart, brain, and spinal cord, suggesting ANH may place the kidneys at risk.[171] Most studies evaluating ANH have focused on a reduction in RBC mass loss and the use of allogenic blood cell transfusions as the primary outcomes. Fewer studies have reported favorable findings with respect to end-organ damage in patients treated with ANH compared with those not treated, but studies in the future should look more closely at these important outcomes.[162]

BOX 49.3 Criteria for Selection of Patients for Acute Normovolemic Hemodilution

1. Likelihood of transfusion exceeding 10% (i.e., blood requested for crossmatch according to a maximum surgical blood order schedule)
2. Preoperative Hb of at least 12 g/dL
3. Absence of clinically significant coronary, pulmonary, renal, or liver disease
4. Absence of severe hypertension
5. Absence of infection and risk of bacteremia

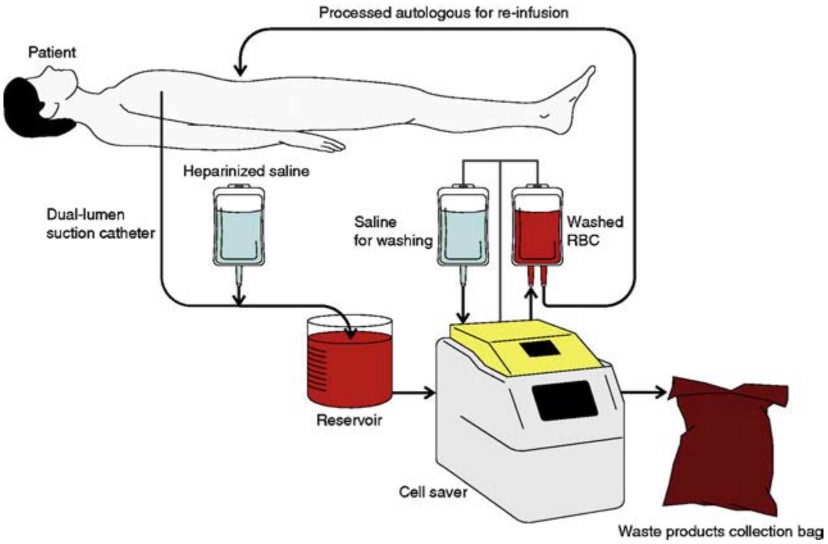
INTRAOPERATIVE CELL SALVAGE

The term *intraoperative blood collection* or *cell salvage* describes the technique of collecting, processing, and reinfusing blood lost by a patient during surgery. It is a perioperative blood conservation technique to reduce use of allogenic blood and the risks associated with allogeneic blood exposure. It may be acceptable for use in patients that do not consent to allogeneic or preoperative autologous blood transfusions, such as Jehovah's Witnesses. This technique should be discussed with such patients and acceptability should be determined on a case-by-case basis.[172]

The AABB continues to recommend the following general indications for cell salvage use in their 2016 guidelines:[173]

1. Anticipated blood loss is 20% or more than the patient's estimated blood volume.
2. Crossmatch-compatible blood is unobtainable.
3. Patient is unwilling to accept allogeneic blood but will consent to receive blood from intraoperative blood salvage.
4. The procedure is likely to require more than one unit of RBCs.

Cell salvage involves the collection of blood from the surgical field through a specialized double-lumen suction tubing that delivers anticoagulant, commonly heparin or citrate, to the tip of the suction catheter (Fig. 49.5). This prevents suctioned blood from clotting within the collection system. Blood from the surgical field is collected in a reservoir until enough fluid accumulates for processing. Processing involves specialized centrifugation that causes the lower density plasma and anticoagulant fluid to rise up and separate from the higher density RBCs, which are collected at the bottom of a conical- or cylindrical-shaped bowl. In general,



Processed autologous for re-infusion
Patient
Heparinized saline
Dual-lumen suction catheter
Saline for washing
Washed RBC
Reservoir

Waste products collection bag

Fig. 49.5 Diagram of the setup of a standard cell salvage circuit. *RBC*, Red blood cell. (From Ashworth A, Klein A. Cell salvage as part of a blood conservation strategy in anaesthesia. *Br J Anaesth*. 2010;105[4]:401–416. https://doi.org/10.1093/bja/aeq244.)

500 to 700 mL of collected blood is required for processing to produce 225 to 250 mL of salvaged saline-suspended PRBCs with a Hct of 50% to 60%.[174] At this point, the salvaged PRBCs are ready for immediate or delayed transfusion. Microaggregate filters (40 µm) are most often employed during reinfusion because recovered and processed blood may contain tissue debris, small blood clots, or bone fragments. Some systems are able to continually process blood and can provide the equivalent of 12 units/h of banked blood to a massively bleeding patient.[175]

The oxygen transport properties and survival of recovered RBCs appears to be equivalent to those of stored allogeneic RBCs. Levels of 2,3-DPG appear to be present at near normal levels in salvaged blood compared with stored allogenic blood cells, which have up to 90% reduction in 2,3-DPG levels.[43] Similarly, the P50 of salvaged blood is similar to that of fresh venous blood drawn from the same patient and significantly higher than that of 2-week old banked blood, suggesting better oxygen-offloading capabilities.[176] RBC deformability also appears improved compared with PRBCs.[41]

Some practical considerations for cell recovery programs are listed in (Box 49.4). If collected under aseptic conditions with a saline-wash device and if properly labeled, blood may be stored at room temperature for up to 4 hours or at 1°C to 6°C for up to 24 hours, provided storage at 1°C to 6°C is begun within 4 hours of ending the collection.[173] The allowable interval of room temperature storage is shorter for recovered blood (4 hours) than for ANH blood (8 hours). Storage times are the same for recovered blood regardless of whether unwashed or washed.

Reinfusion of salvaged blood is not without risk (Box 49.5).[177] Air embolism is a serious, potentially fatal problem, but this risk is now mitigated with newer systems that do not allow for the system's direct connection to the patient's intravenous tubing. Collection systems that neither concentrate nor wash shed blood before reinfusion increase the risk of adverse effects. Shed blood has undergone varying degrees of coagulation or fibrinolysis and hemolysis, and infusion of large volumes of washed or unwashed blood has been associated with disseminated intravascular coagulation (DIC).[178] In general, blood collected at low flow rates or during slow bleeding from patients who are not systemically anticoagulated will have undergone coagulation and fibrinolysis and will not contribute to hemostasis on reinfusion. The high suction pressure and surface skimming during aspiration and the turbulence or mechanical compression that occurs in roller pumps and plastic tubing make some degree of hemolysis inevitable.[179] Patients exhibit a level of plasma-free hemoglobin that is usually higher than after allogeneic transfusion. High concentrations of free hemoglobin can be nephrotoxic to patients and free hemoglobin causes severe arteriolar vasoconstriction of microvascular structures from NO scavenging.[180] However, the clinical importance of this phenomenon in

BOX 49.4 Practical Considerations for Intraoperative Cell Recovery, Storage, and Reinfusion

1. If not transfused immediately, units collected from a sterile operating field and processed with a device for intraoperative blood collection that washes with 0.9% saline should be stored under one of the following conditions before initiation of transfusion:
   a. At room temperature for up to 4 h after terminating collection
   b. At 1°C-6°C for up to 24 h, provided storage at 1°C-6°C is begun within 4 h of ending the collection
2. Transfusion of blood collected intraoperatively by other means should begin within 6 h of initiating the collection.
3. Each unit collected intraoperatively should be labeled with the patient's first name, last name, and hospital identification number; the date and time of initiation of collection and of expiration; and the statement "For Autologous Use Only."
4. If stored in the blood bank, the unit should be handled like any other autologous unit.
5. The transfusion of shed blood collected under postoperative or posttraumatic conditions should begin within 6 h of initiating the collection.

BOX 49.5 Types of Adverse Reactions That May Be Seen With Blood Transfusion from Intraoperative Cell Salvage

Hypervolemia
Bacterial contamination
Hypotension
Nonimmune hemolysis
Immune hemolysis
Febrile nonhemolytic reactions
Allergic reactions
Disseminated intravascular coagulation
Coagulopathies
Air embolus
Reactions secondary to reinfusion of anticoagulants or other contaminants
Nonspecific temperature increases, chills, skin flushing, etc.

From Domen R. Adverse reactions associated with autologous blood transfusion: evaluation and incidence at a large academic hospital. *Transfusion*. 1998;38:296–300. https://doi.org/10.1046/j.1537-2995.1998.38398222875.x

intraoperative cell salvage has not been established. Many programs limit the quantity of recovered blood that may be reinfused without processing. To minimize hemolysis, the vacuum level should ordinarily not exceed 150 mm Hg, although higher levels of suction may occasionally be needed during periods of rapid bleeding. One study found that vacuum settings as high as 300 mm Hg could be used, when necessary, without causing excessive hemolysis.[181]

Positive bacterial cultures from recovered blood are sometimes observed, but clinical infection is rare[182] and may be mitigated with the use of a leukocyte filter in the system[183] Intraoperative collection is contraindicated when certain procoagulant materials (e.g., topical collagen) are applied to the surgical field because systemic activation of coagulation may result. Other instances that may preclude use of cell savage include: use of parenterally incompatible chemicals (e.g., chlorhexidine, betadine, hydrogen peroxide) in the surgical field, and use of hypotonic solutions in the surgical field, which may lyse red blood cells.

Clinical Studies

As with PAD and ANH, collection and recovery of intraoperative autologous blood should undergo scrutiny with regard to both safety and efficacy.[184] A meta-analysis of 75 studies evaluating the utility for cell salvage to minimize allogeneic blood transfusion found that cell salvage reduced the need for allogeneic blood transfusion in adult-elective surgeries by 38%.[185] The greatest benefit was seen in orthopedic procedures but cardiac surgery patients also benefited. On average, intraoperative blood salvage saved an average of 0.68 units of allogenic banked blood. Of note, two randomized controlled trials published in 2014 of patients undergoing hip and knee arthroplasty with either preoperative hemoglobin concentration between 10 to 13 g/dL or more than 13 g/dL failed to show cell salvage as an effective means to reduce allogenic blood requirements.[186,187] However, both studies combined intraoperative and postoperative cell salvage and did not separate patients who received one technique (or both techniques) from those who received another.

TABLE 49.12 Procedures Where Intraoperative Cell Salvage May Be Indicated

General Surgery	Hepatic resection
	Splenectomy
Neurosurgery	Basilar Aneurysm
Transplant Surgery	Liver transplant
	Kidney transplant
Cardio/Thoracic	Cardiac transplant/VAD implant
	Pulmonary transplant
	Coronary artery bypass grafting
	Cardiac valve repair/replacement
	Aortic arch Aneurysm
	Thoracic trauma
Vascular	Aortic Aneurysm repair
	Femoral bypass grafting
Orthopedic	Total shoulder replacement
	Total hip replacement or revision
	Bilateral knee replacement
	Open reduction/internal fixation pelvic or long bone fracture
	Multilevel spine surgery
Urology	Nephrectomy
	Radical prostatectomy
Gynecology	Hysterectomy
Obstetrics	Placenta accreta, increta, or percreta

Adapted from Esper SA, Waters JH. Intra-operative cell salvage: a fresh look at the indications and contraindications. *Blood Transfus*. 2011;9(2):139–147.

In some cases, the value of blood salvage may not be in terms of patient outcome or reduction of transfusion requirements, but instead in cost savings. The value of intraoperative blood collection was recently demonstrated for high-risk cesarean surgeries but not for routine procedures.[188] A list of surgeries where intraoperative cell salvage may be indicated are provided in Table 49.12. As comprehensive PBM pathways continue to evolve and improve patient outcomes, future studies regarding the efficacy and cost-effectiveness of cell salvage will be needed.

POSTOPERATIVE CELL SALVAGE

Postoperative blood collection denotes the recovery of blood from surgical drains followed by reinfusion, with or without processing.[166] In some programs, postoperative shed blood is collected into sterile canisters and reinfused, without processing, through a microaggregate filter. Recovered blood is dilute, is partially hemolyzed, and may contain high concentrations of cytokines. For these reasons, most programs set an upper limit on the volume (e.g., 1400 mL) of unprocessed blood that can be reinfused. If transfusion of blood has not begun within 6 hours of initiating the

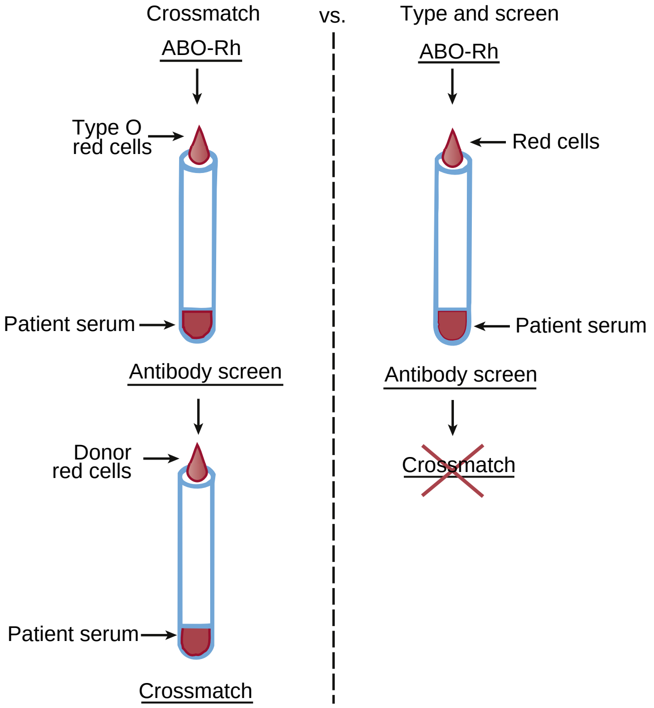

Fig. 49.6 Outline of the tests used for a crossmatch. The X over the word *crossmatch* means that the crossmatch is not included in the type and screen.

collection, the blood must be discarded. Although this technique gained popularity for total joint arthroplasties, the technique is being used less frequently because of a number of factors, including improved PBM programs, lack of evidence for effectiveness, and care pathways that lead to earlier hospital discharge.[174]

Compatibility Testing

GENERAL PRINCIPLES

The ABO-Rh type, antibody screen, and crossmatch are frequently referred to as compatibility tests. These tests were designed to demonstrate harmful antigen-antibody interactions in vitro so that harmful in vivo antigen-antibody interactions can be prevented. Donor blood used for emergency transfusion of type-specific blood must be screened for hemolytic anti-A and/or anti-B antibodies, and Rh antibodies. Similarly, recipient blood must also undergo ABO-Rh typing, as well as testing for unexpected antibodies. Once this has been completed, proper selection of donor blood requires a crossmatch to test for compatibility between recipient blood and donor blood (Fig. 49.6). All approved blood banks have redundant processes in place to ensure that the patient receives the correct unit of blood. Most will require a second confirmatory specimen drawn on a separate occasion from the first type and screen to reduce the risk of a crossmatch error and a hemolytic blood transfusion reaction.[189]

ABO-RH TYPING

Determination of the patient's correct blood type is exceedingly important because the most serious and tragic reactions are usually caused by accidental transfusion of ABO-incompatible blood. In fact, 15% of all transfusion-related deaths are related to hemolytic reactions due to antibody incompatibility.[190] These reactions result from naturally occurring antibodies (i.e., anti-A and anti-B), which activate complement and lead to rapid intravenous hemolysis. Anti-A or anti-B antibodies are formed whenever the individual lacks either or both of the A and B antigens. ABO typing is performed by testing RBCs for the A and B antigens and the serum for the A and B antibodies before transfusion (Table 49.13).

TABLE 49.13 ABO Compatibility Testing

	RED CELLS TESTED WITH		SERUM TESTED WITH	
Blood Group	**Anti-A**	**Anti-B**	**A Cells**	**B Cells**
A	+	–	–	+
B	–	+	+	–
AB	+	+	–	–
O	–	–	+	+

TABLE 49.14 Donor Blood Groups That Patients Can Receive

Donor	Recipient
O	O, A, B, AB
A	A, AB
B	B, AB
AB	AB

The second most important testing is that for the Rh(D) antigen. Antigen D is very common, and, except for the A and B antigens, the one most likely to produce immunization. Of Rh(D)-negative recipients, 60% to 70% of patients given Rh(D)-positive blood produce anti-D antibodies. Anti-D antibodies may also be formed in the Rh(D)-negative parturient. Approximately 85% of individuals possess the D antigen and are classified as Rh(D) positive; the remaining 15%, who lack the D antigen, are classified as Rh(D) negative. Transfusion of Rh(D)-positive blood to a Rh(D)-negative patient with Rh(D) antibodies may produce a hemolytic transfusion reaction. Table 49.14 identifies compatible donor/recipient blood types.

ANTIBODY SCREENING

Antibody screens are performed to identify unexpected RBC alloantibodies. The patient's serum is combined with commercially supplied RBCs that are specifically selected due to their expression of RBC antigens for which clinically significant alloantibodies are formed.[191] The reagent RBCs are type O so they do not react to anti-A or anti-B antibodies that may be present in the patient's serum. Alloantibodies are typically immunoglobulin (Ig)G, and thus do not readily produce agglutination in vitro, but do so in vivo. As a result, an indirect antiglobulin test (formerly an indirect Coombs test) is undertaken to evaluate for the presence of IgG alloantibodies. The patient's serum is combined with the reagent RBCs with an additive that promotes binding of antibodies to the RBCs. The mixture is incubated at 37°C, washed and mixed with reagent containing antibodies to IgG and complement. The reagent binds to any IgG attached to the RBCs, crosslinking the RBCs and producing agglutination in vitro. If the test is positive, follow-up testing must be undertaken to identify the target antigen.

The screen for unexpected antibodies is also used on donor serum and is performed shortly after withdrawal of blood from the donor. It is necessary to screen donor serum for unexpected antibodies to prevent their introduction into the recipient's serum.

Daratumumab, a human monoclonal antibody targeting the CD38 glycoprotein was recently approved for the treatment of multiple myeloma, and has been noted to interfere with antibody screening. The drug binds to CD38 expressed on reagent RBCs, leading to a potentially false positive result.[192] Treatment of reagent RBCs with dithiothreitol negates the interference but also leads to denaturing Kell antigens; therefore, K^- RBC units should be allocated in this circumstance unless the patient is known to be K^+.[193] As immunotherapeutic agents and their indications expand, anesthesiologists should be aware of their implications to antibody screening to allow for appropriate testing to avoid delays in the allocation of blood products.[194]

CROSSMATCHING

A crossmatch is a trial transfusion within a test tube in which donor RBCs are mixed with recipient serum to detect a potential for transfusion reaction. The full crossmatch can be completed in 45 to 60 minutes and is performed in three phases: an immediate spin (IS) phase, an incubation phase, and an indirect antiglobulin phase.

First, the IS phase is conducted at room temperature and is a check against errors in ABO typing. It detects ABO incompatibilities and those caused by naturally occurring antibodies in the MN, P, and Lewis systems, but is insensitive to the presence of other RBC alloantibodies. This takes 1 to 5 minutes to complete. In the setting of a negative antibody screen or during emergency situations when an abbreviated crossmatching process is required, this step may serve as the sole confirmatory process to eliminate reactions that may result from human errors in ABO-Rh typing alone. Blood given after this test is more than 99% safe in terms of avoiding incompatible transfusion reactions caused by unexpected antibodies.[195]

Next, the incubation and indirect globulin or "indirect Coombs" phases primarily detect antibodies in the Rh system and other non-ABO blood group systems.[196] This two-step process involves incubation of the test tube at 37°C in albumin or low–ionic strength salt solution, which aids in the detection of incomplete antibodies or antibodies able to attach to a specific antigen (i.e., sensitization) but are unable to cause agglutination in a saline suspension of RBCs. An incubation period of 30 to 45 minutes in albumin and 10 to 20 minutes in low–ionic strength salt solution in this phase is of sufficient duration to allow antibody binding to cells so that incomplete antibodies missed in this phase can be detected in the subsequent antiglobulin phase. The RBCs are centrifuged, resuspended, and observed for hemolysis and agglutination. The RBCs are then washed and resuspended in solution to remove unbound immunoglobulins. Antiglobulin sera is added to the test tubes. The antihuman antibodies present in the sera become attached to the antibody on the RBCs, causing agglutination. This antiglobulin phase detects most incomplete antibodies in the blood group systems, including the Rh, Kell, Kidd, and Duffy blood group systems.

The incubation and antiglobulin phases are important because the antibodies appearing in these phases are capable of causing serious hemolytic reactions. Except for hemolytic reactions involving anti-A and anti-B, reactions caused by antibodies appearing in the immediate phase are frequently less severe as many are naturally occurring, present in low titers, and not reactive at physiologic temperatures.

ELECTRONIC CROSSMATCH

In previously transfused or pregnant patients, only 1 patient in 100 may have an irregular antibody other than the anti-A and anti-B antibodies. However, some of these irregular antibodies are reactive only at temperatures below 30°C and therefore are insignificant in most transfusions. Others that are reactive at approximately 30°C can produce serious reactions if the transfused cells contain the appropriate antigen. In order of probable significance, anti-Rh(D), Kell, C, E, and Kidd are the most common of clinically significant antibodies. If the correct ABO and Rh blood type is given, the possibility of transfusing incompatible blood is less than 1 in 1000. ABO-Rh typing alone results in a 99.8% chance of a compatible transfusion, the addition of an antibody screen increases the safety to 99.94%, and a crossmatch increases this to 99.95%.[197] Complete transfusion testing for compatibility between donor and recipient blood ensures optimal safety and therapeutic effect of transfused blood, but the process is time-consuming and costly.

Once a serologic crossmatch is complete, blood is allocated and set aside for that patient for up to 72 hours. If unused, the product is returned to circulation for other potential recipients. This practice leads to the loss of use for that blood product and increases the chance for outdating of unused products. Eliminating the serologic crossmatch and replacing it with a type and screen followed by a computerized or electronic crossmatch improves the efficiency of the blood banking system, while maintaining, if not improving, patient safety.[198] According to FDA guidance in the United States, a computerized match requires that software determine if incompatibility exists between donor and recipient. Decisions are made based on two separate ABO/Rh typing results from separate specimens from both the donor and the recipient. Under usual perioperative circumstances, measuring the two results from a single specimen should be avoided, as a major cause of ABO errors is a mislabeled specimen.[199] Mislabeling of specimens occurs with an incidence of more than 7 per 1000 specimens with "wrong blood in tube" occurring at a rate of 0.4 instances per 1000 specimens.[200] Interestingly, in this study by Novis and associates, the incident error rate did not decrease between the years of 2007 and 2015, despite the institution of barcode scanning.

A clinically significant current or previously detected positive antibody screen excludes the use of the electronic crossmatch and a serologic crossmatch should be performed.[201]

Patients with a history of a clinically significant antibody despite a current negative antibody screen should continue to be excluded from the electronic crossmatch. The concern is that low titers of circulating antibodies can produce a falsely negative antibody screen.[202]

The type and screen without the serologic crossmatch does not protect against reactions caused by antibodies reactive against lower incidence antigens. These are antigens not represented on the screening cells but present on the donor RBCs. In general, antibodies that are not detected in the type and screen are weakly reactive antibodies that do not result in serious hemolytic transfusion reactions. In a study of 13,950 patients, Oberman and associates[203] discovered only eight "clinically significant" antibodies after complete crossmatch that were not detected during the antibody screening. The antibodies were all in lower titer and were believed to be unlikely to cause serious hemolytic reactions.

Maximal Surgical Blood Order Schedule

In the 1960s and 1970s, the number of crossmatched units ordered for certain surgical procedures frequently far exceeded the number actually transfused. This led to blood being set aside and potential outdating. To better quantify this problem, the crossmatch-to-transfusion (C/T) ratio has been used. If the C/T ratio is high, a blood bank is burdened with keeping a large blood inventory, using excessive personnel time, and having a high incidence of outdated units. Sarma[204] recommended that for surgical procedures in which the average number of units transfused per case is less than 0.5, determination of the ABO-Rh type and a screen of the patient serum for unexpected antibodies (type and screen) should be used. This would be in lieu of a complete crossmatch for patients with negative antibody screens. More recently, Dexter and associates[205] established that using the estimated blood loss reported in an anesthesia information system is more efficacious at predicting the need for transfusions. Their data indicated that for surgical procedures with less than 50 mL expected blood loss, a type and screen is not required.

To increase the rate of use and lower the C/T ratio, blood banks attempt to decrease the emphasis on crossmatching of blood through such programs as the maximal surgical blood order schedule (MSBOS).[206] Ideally, blood banks aim to maintain C/T ratio of less than 2.[207] The MSBOS consists of a list of surgical procedures and the maximal number of units of blood that the blood bank will crossmatch for each procedure. This schedule is based on the blood transfusion experience for surgical cases in a hospital. Each hospital's MSBOS is unique to that practice. The implementation of the MSBOS resulted in a decrease of blood unit expiration from 6.5% to 4.5% at the University of Michigan.[208] Subsequently, patients were categorized into one of three groups: (1) requiring a crossmatch, (2) requiring a type and screen, or (3) no sample required. Preoperative blood orders decreased by 38% with a C/T ratio that decreased by 27%. However, the authors noted the rate of emergency release RBC units increased from 2.2 to 3.1 patients per 1000, but 60% of those patients requiring emergency release blood were undergoing emergency surgery. Of the patients in the "no sample required" category, only a marginal increase of 0.4 to 1 per 1000 patients requiring emergency release blood was noted.[209]

Instead of the blood bank examining the next day's surgical schedule and allocating blood as described in the previous paragraph, now information technology systems have the capability of displaying the surgical schedule along with the MSBOS's recommendation regarding blood preparation. The night before, the blood bank examines the surgical schedule and MSBOS recommendations to see whether blood is needed. The blood bank also uses the MSBOS information to see if additional testing should be performed. Missing tests are communicated to the primary team so that appropriate orders can be placed.

Emergency Transfusion

In many situations, urgent need for blood occurs before completion of compatibility testing (ABO-Rh typing, antibody screen, or crossmatch; see also Chapter 66, which describes transfusion challenges in patients who require surgery and anesthesia after injury from trauma). In essence, for those situations that do not allow time for complete testing, an abbreviated format for testing can be used or uncrossmatched group O blood can be allocated. The procedures described in the following paragraphs aim to provide the potentially life-saving blood product, while minimizing the risk for acute, intravascular hemolytic transfusion reactions.

TYPE-SPECIFIC, PARTIALLY CROSSMATCHED BLOOD

When using uncrossmatched blood, it is best to obtain at least an ABO-Rh typing and an immediate-phase crossmatch. This incomplete crossmatch is accomplished by adding the patient's serum to donor RBCs at room temperature, centrifuging it, and then reading it for macroscopic agglutination. This takes 1 to 5 minutes and eliminates serious hemolytic reactions resulting from errors that may occur in ABO typing. Only a few unexpected antibodies outside the ABO systems are detected, such as those directed against antigens in the MN, P, and Lewis systems, most of which are not clinically significant.

TYPE-SPECIFIC, UNCROSSMATCHED BLOOD

For proper use of type-specific blood, the ABO-Rh type must be determined during the patient's hospitalization. Reports of blood type from patients, relatives, outside medical records may be inaccurate. For those who have never been exposed to foreign RBCs, most ABO type-specific transfusions are successful. Caution should be used for patients who have previously received transfusions or have been pregnant. Historically, in the military, type-specific uncrossmatched blood has been used in emergencies with no serious consequence. In the civilian setting, using 1 year's experience with 56 patients, uncrossmatched, type-specific blood for emergency transfusion produced no adverse effects.[210] The investigators concluded that although the use of uncrossmatched blood is usually safe, the potential for serious reaction still exists, and they cautioned against its indiscriminate use. For those who have previously been exposed to RBC antigens, transfusion of the ABO-Rh type-specific, uncrossmatched blood may be more hazardous.

TYPE O RH-NEGATIVE (UNIVERSAL DONOR), UNCROSSMATCHED BLOOD

Type O blood lacks A and B antigens and consequently cannot be hemolyzed by anti-A or anti-B antibodies in the recipient's plasma (see Tables 49.13 and 49.14). Type O blood can be used for transfusions when typing or crossmatching is not available. However, some type O donors produce high titers of hemolytic IgG, IgM, anti-A, and anti-B antibodies. High titers of these hemolysins in donor units are capable of causing destruction of A or B RBCs of a non–type O recipient. Type O Rh-negative, uncrossmatched PRBCs should be used in preference to type O Rh-negative whole blood because packed erythrocytes have smaller volumes of plasma and are almost free of hemolytic anti-A and anti-B antibodies. If type O Rh-negative whole blood is to be used, the blood bank must supply type O blood that is previously determined to be free of hemolytic anti-A and anti-B antibodies.

Some hospitals have an emergency-release pack of uncrossmatched O negative RBCs. This blood usually can be provided in approximately 5 minutes for urgent situations. Also available in some hospitals is a massive transfusion protocol (MTP), which provides 4 units uncrossmatched O negative RBCs, 4 units thawed AB plasma, and 1 unit of platelet concentrates. Use of MTP blood is determined by physician judgment, but that decision is reviewed after the emergency situation. Although uncrossmatched blood appropriately causes great concern, the risks for complication appear to be quite infrequent.[211] Boisen and associates describe only a 0.1% occurrence of detectable hemolysis in the transfusion of 10,916 uncrossmatched units in 2906 patients.[212] Also, in patients transfused with uncrossmatched blood with antigens for which they are later found to have antibodies against, only 7 out of 262 patients experienced hemolytic reactions.[213]

If emergency transfusion of more than 2 units of type O Rh-negative, uncrossmatched whole blood is used, the patient cannot be switched to his or her blood type (A, B, or AB) once that is determined. Switching could cause major intravascular hemolysis of donor RBCs because of high titers of transfused anti-A and anti-B. Continued use of O Rh-negative whole blood results only in minor hemolysis of recipient RBCs and hyperbilirubinemia. The patient must not be transfused with his or her correct blood type until the blood bank determines that the transfused anti-A and anti-B has decreased to levels that permit safe transfusion of type-specific blood.

Fresh Whole Blood

The definition of fresh whole blood is based on storage time, which varies widely in the literature.[214] Some investigators[215] define fresh blood as blood stored at 1°C to 6°C within 8 hours after collection and used within 24 hours, while other investigators define it as fresh if it has been stored less than 48 hours at 2°C to 5°C. The degree to which fresh blood regains its various functions is directly related to the length of storage and whether it has been cooled. The longer blood is stored, the less effective it becomes, especially regarding coagulation. Whole blood stored for 24 hours at 4°C has less hemostatic effects than blood stored for less than 6 hours because of decreased platelet aggregability.[216] Whole blood that has been typed and crossmatched, but not cooled, retains most of the factors of normal in vivo blood. The difference between 1 hour and 2 days of storage can be tremendous and may impact clinical outcomes.

Numerous studies have examined the use and safety of fresh whole blood, particularly by the U.S. military in Iraq and Afghanistan.[217] Whole blood has been a component of transfusion for over 70 years.[9] Experience in Vietnam showed that typed and crossmatched warm whole blood was extremely effective in treating the coagulopathy from massive transfusions.[2,3,218]

Complications

COAGULATION ABNORMALITIES

Major trauma or blood loss will initiate a cascade of coagulation abnormalities, including a consumptive coagulopathy from tissue hypoperfusion as manifested by increased protein C levels.[219] This coagulopathy is caused by a combination of factors, of which the most important are the dilution of coagulation factors by volume administration (e.g., crystalloid, colloid, PRBC), and the duration of hypotension and hypoperfusion. Various protocols have been developed for approaches to massive blood transfusion administration (Fig. 49.7). Patients who have adequate perfusion and are not hypotensive for a long period (e.g., 1 hour or less) may tolerate administration of multiple units of blood without developing a coagulopathy. The patient who is hypotensive and has received many units of RBCs will develop a coagulopathy that resembles DIC. When such bleeding occurs, the differential diagnosis is dilutional thrombocytopenia, deficiency of factors V and VIII, a DIC-like syndrome, or a transfusion reaction. Clinical signs include oozing into the surgical field, hematuria, gingival bleeding, petechia, bleeding from venipuncture sites, and ecchymosis.

THROMBOCYTOPENIA

Thrombocytopenia is defined as a platelet count less than 150×10^9/L or more than 50% decrease compared with the previous measurement. Clinical bleeding usually does not occur during surgery until platelet counts are less than 50×10^9/L and for spontaneous bleeding until platelet counts are less than 10×10^9/L.[220] Independent of whether whole blood or PRBCs are given, few viable platelets exist in a unit of blood stored for more than 24 hours. For whole blood stored at 4°C, platelets are damaged sufficiently to be readily trapped and absorbed by the reticuloendothelial system soon after infusion. Even platelets that are not immediately stored have a reduced survival time.

Thrombocytopenia can trigger a hemorrhagic diathesis in a patient who has received multiple units of bank blood.

Fig. 49.7 This algorithm for diagnosing and treating a massive transfusion was modified from the massive transfusion protocol used at the San Francisco General Hospital. This protocol suggests how to approach a patient with major blood loss. *BP,* Blood pressure; *CBC,* complete blood cell count; *EBV,* effective blood volume; *ED,* emergency department; *FFP,* fresh frozen plasma; *Hct,* hematocrit; *INR,* international normalized ratio; *PC,* platelet count; *PRBCs,* packed red blood cells; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

Platelet counts decreased to less than 100 × 10^9/L when 10 to 15 units of blood were given to acutely wounded, previously healthy soldiers.[219] Miller and colleagues[2] found that platelet counts less than 75 × 10^9/L are a reasonably accurate guide as to when patients will develop a bleeding problem from dilutional thrombocytopenia (see Table 49.10). One trauma group suggests that a higher than normal platelet count may be required in severely injured trauma patients[222] to maintain adequate hemostasis because damaged capillaries require platelets to "plug the holes." The military and trauma hospitals tend to follow transfusion ratios and do not follow strict platelet thresholds for transfusion.

Several investigators[223,224] have questioned the role of dilutional thrombocytopenia in the coagulopathy of massively transfused patients. They point out that the platelet count rarely decreases to as low a level as would be predicted from dilution alone (Fig. 49.8). It may be that platelets are released into the circulation from the spleen and bone marrow but that some of the platelets present function poorly. Patients with chronic thrombocytopenia or leukemia often do not have a hemorrhagic diathesis with a platelet count lower than 15 × 10^9/L. For unexplained reasons, patients with an acute induced thrombocytopenia (e.g., from blood transfusions) develop a hemorrhagic diathesis at a much higher platelet count than patients with chronic thrombocytopenia (e.g., idiopathic thrombocytopenic purpura).

Most would agree that platelets should not be given to treat laboratory evidence of thrombocytopenia unless

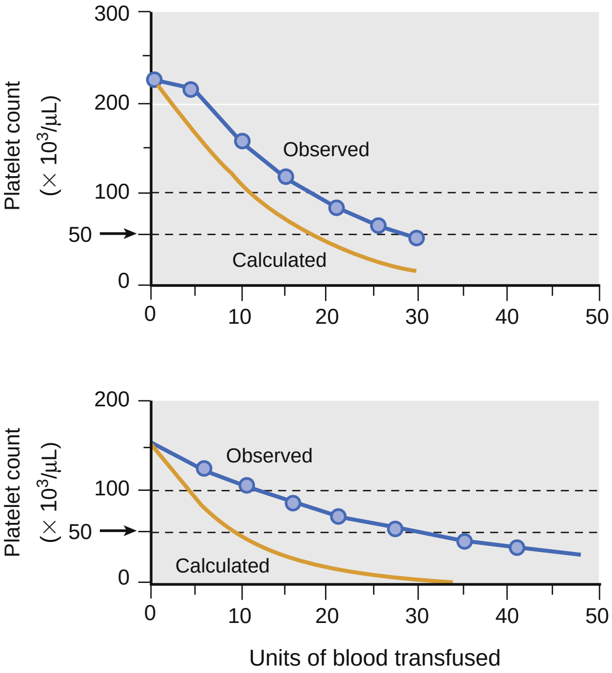

Fig. 49.8 Mean platelet counts after massive transfusions in relation to number of units of blood transfused. Observed versus predicted values calculated on the basis of 2 blood exchange models. (From Myllylä G. New transfusion practice and haemostasis. *Acta Anaesthesiol Scand. Suppl.* 1988;89:76.)

clinical coagulopathy is also present. Treating laboratory numbers without correlation with the clinical status is fundamentally contrary to good medical practice. When the platelet count is less than 50 to 70 × 10^9/L, coagulation is likely impaired due to a combination of dilutional thrombocytopenia and DIC. In many cases, certainly with a concomitant medical condition (e.g., DIC, sepsis), the platelet count as a result of dilutional thrombocytopenia cannot be predicted,[225] nor can the actual impact on clinical bleeding. This is just one of the reasons why efficacy of blood product administration is often difficult to assess. Growing use of point-of-care viscoelastic tests such as tTEG and rotational thromboelastometry instead of platelet count to guide hemostatic therapy is becoming more common.[226]

LOW LEVELS OF FIBRINOGEN AND FACTORS V AND VIII

Considerable attention has been paid to the decreases in blood fibrinogen concentrations that occur during blood loss and blood replacement, likely due to the availability of a lyophilized fibrinogen concentrate for clinical use. Fibrinogen supplementation was previously provided by administration of FFP and cryoprecipitate. Levy and colleagues[227] provided an excellent scholarly review of fibrinogen and hemostasis and concluded that fibrinogen is critical for effective clot formation, and its monitoring and supplementation as the treatment of major bleeding should be recognized. Many prospective studies of fibrinogen supplementation in acquired bleeding report that it is the most effective method of supplementation, and a comprehensive safety profile of fibrinogen concentrate is beginning to appear.

Factors V and VIII may also be affected during storage and significant transfusion.[228] These factors decrease to 50% and 30% of normal, respectively, in whole blood after 21 days of storage[229] and are not present in units of PRBCs. By 35 days of storage, factor V and factor VIII fall further to approximately 20% activity of normal.[230]

Administration of FFP, which contains all the factors, has been recommended. However, this practice is of questionable benefit because only 5% to 20% of factor V and 30% of factor VIII are needed for adequate hemostasis during surgery, and even during massive blood transfusion, factors V and VIII rarely decrease below those levels.

DISSEMINATED INTRAVASCULAR COAGULATION–LIKE SYNDROME

The coagulation system consists of clotting and fibrinolytic mechanisms. The function of the former is to prevent excessive blood loss, and that of the latter is to ensure circulation within the vasculature. With this DIC-like syndrome, the clotting system is deranged, leading to disseminated fibrin deposition, which renders the blood unclottable. The deposited fibrin may severely alter the microcirculation and lead to ischemic necrosis in various organs, particularly the kidney. Table 49.15 displays the interchange between various medical conditions and their impact on various measures of the coagulation system.[231]

The specific reasons for the development of DIC syndrome are usually not apparent. However, hypoxic acidotic tissues with stagnant blood flow probably release tissue thromboplastin directly or through the protein C pathway.[219] The release of tissue plasminogen activator from damaged tissue may cause fibrinolysis. The coagulation system is activated by tumor necrosis factor and endotoxins, resulting in consumption of factors I, II, V, and VIII, and platelets. In an attempt to counteract the hypercoagulable state, the fibrinolytic system is activated to lyse the excessive fibrin. If enough thromboplastin lodges in the circulating blood, the result is massive focal necrosis or more generalized activation of the coagulation system.

DIAGNOSIS AND TREATMENT OF A HEMORRHAGIC DIATHESIS AFTER BLOOD TRANSFUSIONS

Although treatment is more likely to be successful when the cause of the bleeding problem has been identified, precise diagnosis is often difficult. In addition to clinical examination of the patient, various coagulation laboratory tests may be helpful. One traditional approach has been to obtain a blood sample for platelet count, PTT, and plasma fibrinogen level; observation of a clot for size, stability, and lysis; and observation of the plasma for evidence of hemolysis. If the PTT is 1.5 times normal or more and other tests are normal, the bleeding is probably a result of very low levels of factors V and VIII. This can be treated with FFP or with cryoprecipitate (Fig. 49.9).

Whether platelets are administered in the form of fresh blood, platelet-rich plasma, or platelet concentrates depends on intravascular volume replacement requirements, personal preference, and availability of laboratory personnel. Fresh blood (<6 hours old) supplies the

largest number of platelets per donation. More than 80% of the platelets can be given by platelet-rich plasma, which has half of the volume of a unit of blood. However, because most blood banks only have components, platelet concentrates are frequently recommended. Platelet concentrates are contained in a 50-mL unit and provide approximately 70% of the platelets in a unit of blood. In a 70-kg person, approximately 10 units of platelet concentrates are required to increase the platelet count by 10 × 10^9/L in absence of a consumptive process. Although logistically difficult to obtain, fresh blood is extremely effective in treating transfusion-induced coagulopathies. Lavee and associates[232] found that 1 unit of fresh whole blood was as effective as, if not superior to, 8 to 10 platelet units.

Determining the plasma fibrinogen level is useful because this coagulation factor does not decrease in whole blood. If the in vivo plasma fibrinogen level is low (<150 mg/dL), it is not a result of a dilutional coagulopathy and strongly suggests DIC or a DIC-like syndrome. DIC is likely with thrombocytopenia, hypofibrinogenemia, and lysis of clot.[228] With much less plasma, dilution of certain coagulation values may be more profound with the use of PRBCs rather than whole blood. With use of PRBCs, fibrinogen levels decreased significantly in contrast to use of whole blood, in which fibrinogen levels remained unchanged unless DIC is present (Fig. 49.10).[233]

An algorithm for the evaluation and initial therapy of a patient with a suspected coagulopathy is given in Fig. 49.11 (see also the section on blood transfusions, pharmacology, and hemostasis).

Citrate Intoxication and Hyperkalemia

Citrate intoxication leads to hypocalcemia, dysrhythmia, and hypotension due to the sequestration of ionized calcium by citrate. The probability of citrate intoxication is increased in pediatric populations[234] and in the setting of hyperventilation, liver disease, and liver transplantation. Infusion of more than 1 unit of blood every 10 minutes can lead to decreasing ionized Ca^{2+} levels. Even at these rates of infusion, ionized calcium levels do not decrease enough to cause bleeding. Citrate reactions in the setting of apheresis for donation of blood components, however, are more common and in one study occurred in more than 5% of donations.[235]

Similar to citrate intoxication, hyperkalemia as a result of transfusion is relatively rare. Although hyperkalemia is occasionally reported,[234,236] large amounts of blood must be given. Even though serum K^+ levels may be as high as 19 to 50 mEq/L in blood stored for 21 days,[237] the net gain of K^+ is

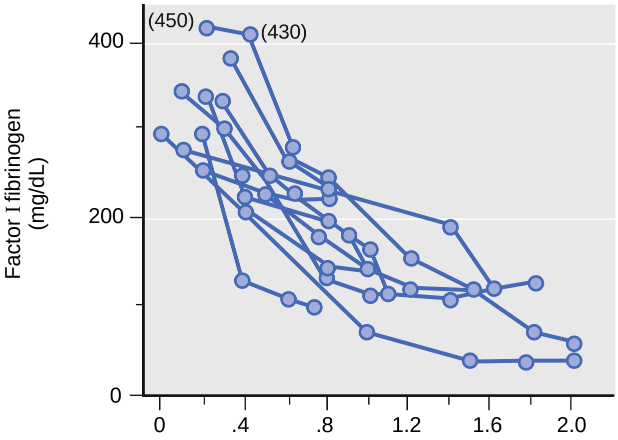

Fig. 49.10 Decreases in fibrinogen level as blood volume is replaced with Adsol-packed red blood cells and crystalloid solutions. Each patient is represented by a solid line. (From Murray DJ, Olson J, Strauss R, et al. Coagulation changes during packed red cell replacement of major blood loss. *Anesthesiology.* 1988;69:839.)

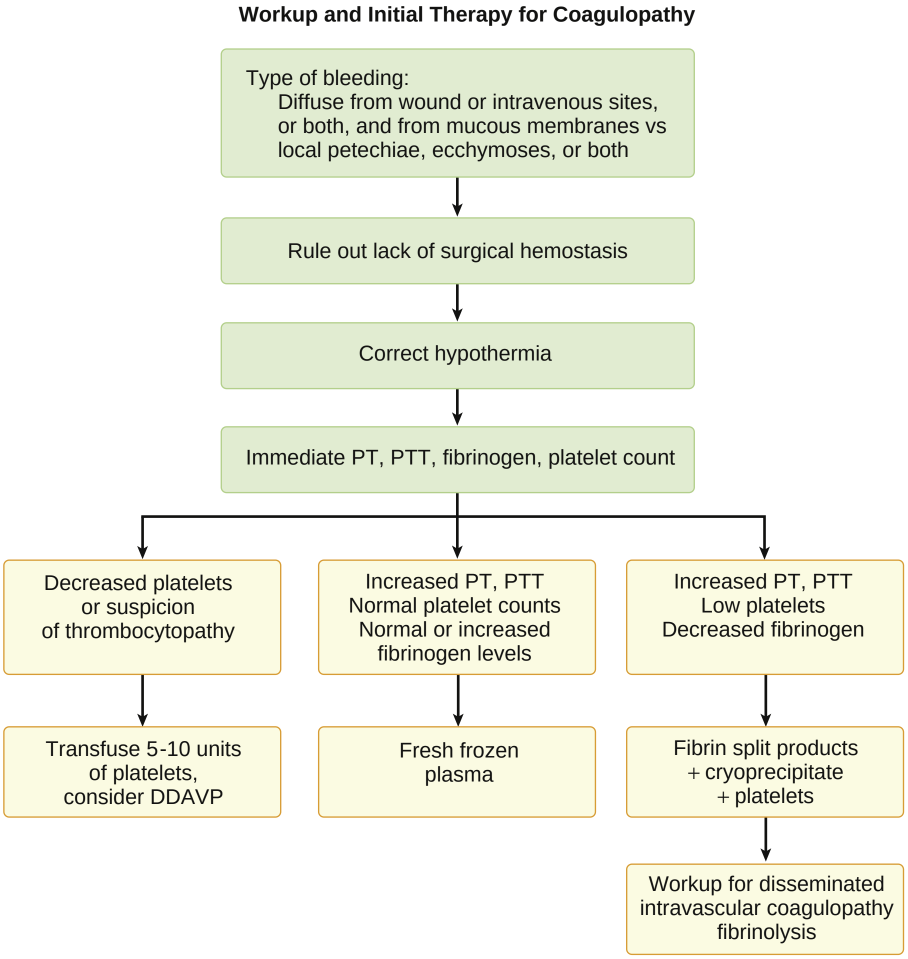
approximately only 10 mEq/L when the loss of K^+ via blood loss is taken into account. For clinically significant hyperkalemia to occur, banked blood must be given at a rate of 120 mL/minute or more. Although still rare, hyperkalemia can occur more frequently in patients with impaired renal function.[238]

Temperature

Administration of blood that has been stored at 4°C can decrease the recipient's temperature and should be avoided if possible due to complications from hypothermia. Hypothermia can interfere with the coagulation process. Even small decreases in body temperature can significantly impair coagulation factors and platelet function.[239] If the temperature decreases to less than 30°C, ventricular irritability and cardiac arrest may occur. Shivering from even mild hypothermia increases metabolic demands and is counterproductive to tissue perfusion, especially in settings where anemia or hypoperfusion is contributing to tissue ischemia.[240]



Workup and Initial Therapy for Coagulopathy
Type of bleeding:
Diffuse from wound or intravenous sites, or both, and from mucous membranes vs local petechiae, ecchymoses, or both
Rule out lack of surgical hemostasis
Correct hypothermia
Immediate PT, PTT, fibrinogen, platelet count
Decreased platelets or suspicion of thrombocytopathy
Increased PT, PTT Normal platelet counts Normal or increased fibrinogen levels
Increased PT, PTT Low platelets Decreased fibrinogen
Transfuse 5-10 units of platelets, consider DDAVP
Fresh frozen plasma
Fibrin split products + cryoprecipitate + platelets
Workup for disseminated intravascular coagulopathy fibrinolysis

Fig. 49.11 Algorithm for the evaluation and initial therapy of a patient with suspected perioperative coagulopathy. The evaluation is based on the clinical scenario and is affected by the type and location of injury, the amount of fluid administered, and the age and body temperature of the patient. *DDAVP,* 1-Deamino-8-D-arginine vasopressin, a vasopressin analogue also known as desmopressin acetate; *PT,* prothrombin time; *PTT,* partial thromboplastin time. Fig. 49.12 Correlation between the amount of blood administered (milliliters) and intraoperative base excess. *ACD,* Acid citrate dextrose. (From Miller RD, Tong MJ, Robbins TO. Effects of massive transfusion of blood on acid-base balance. *JAMA.* 1971;216:1762.)

Maintaining a patient's normal temperature is considered to be increasingly important. Decreases in body temperature can be prevented by warming the blood to body temperature before transfusing. Perhaps the safest and most common method of warming blood is to pass it through plastic coils or plastic cassettes in a warm water (37°C-38°C) bath or warming plates. These heat exchangers should have upper (e.g., 43°C) and lower (e.g., 33°C) temperature limits.

Acid-Base Abnormalities

The pH of most storage media is very acidic (e.g., pH 5.5 for CPD). When this solution is added to a unit of freshly drawn blood, the pH of the blood immediately decreases from 7.4 to 7.1. As a result of accumulation of lactic and pyruvic acids by RBC metabolism and glycolysis, the pH of bank blood continues to decrease to approximately 6.9 after 21 days of storage. A large portion of the acidosis can be accounted for by the carbon dioxide partial pressure (P_{CO_2}) of 150 to 220 mm Hg. P_{CO_2} is high mainly because the plastic container of blood does not provide an escape mechanism for carbon dioxide. With adequate ventilation in the recipient, the high P_{CO_2} should be of little consequence.

Even when the P_{CO_2} is returned to 40 mm Hg, a metabolic acidosis can be still present in blood (see Table 49.4). The metabolic acid-base response to blood transfusion can be quite variable (Fig. 49.12).[241] The empirical administration of sodium bicarbonate is not indicated because of these unpredictable acid-base changes, but administration should be guided by analyses of arterial blood gases.[242] Blood transfusions provide citrate, which can lead to the endogenous generation of bicarbonate. In some patients, this leads to a significant incidence of metabolic alkalosis after blood transfusions.[242]

Transfusion Reactions

HEMOLYTIC TRANSFUSION REACTION

One of the most catastrophic transfusion reactions is intravascular hemolysis. Intravascular hemolysis occurs when there is a direct attack on transfused donor cells by recipient antibody and complement. Such a reaction can occur from infusion of as little as 10 mL of blood.[243] If properly treated, death is rare.[244] However, prevention of renal failure and DIC is crucial. Hemolytic transfusion reactions involving extravascular RBC destruction are generally less serious than those of the intravascular variety. In these cases, recipient antibody coats but does not immediately hemolyze the transfused RBCs and destruction occurs primarily in the reticuloendothelial system.

Since 1975, the FDA has required that all fatal reactions occurring in blood recipients or donors be reported within 24 hours by telephone or within 7 days in writing by all FDA-registered transfusion services. From 1976 to 1985, 328 deaths were reported and analyzed.[245] Of these deaths, 159 were acute hemolytic reactions and 23 from delayed reactions. Of the 159 deaths from acute hemolytic reactions, 137 were caused by errors involving ABO incompatibility. More than half of these errors occurred after the blood had been issued by the blood bank and were committed by practitioners administering blood products to the patient in the operating room, emergency department, ICU, or ward. In 2011, the incidence of an acute hemolytic transfusion reaction resulting from ABO incompatibility was 1:1200 to 1:190,000.[246] The incidence of hemolytic transfusion reactions is sufficient enough that The Joint Commission[244] requires peer-review programs to reduce transfusion errors and complications. Specifically, two patient identifiers and confirmation of the correct blood product are required before a blood product can be given. New technologies are being used to facilitate a decreased incidence of transfusion-related errors such as barcode scanning of blood prior to administration.

Signs and Symptoms

The classic signs and symptoms (Table 49.16) of a hemolytic transfusion reaction—chills, fever, chest and flank pain, and nausea—are masked by anesthesia. Under general anesthesia, hemoglobinuria, bleeding diathesis, or hypotension may be the only clue. The presenting sign is usually hemoglobinuria. As little as 50 mL of incompatible blood may exceed the binding capacity of haptoglobin, which is a protein that can bind approximately 100 mg of Hb/100 mL of plasma. Usually, free hemoglobin circulates as a complex with haptoglobin, which is cleared by the reticuloendothelial system (Fig. 49.13). A sample of plasma that contains 2 mg/dL of Hb is faintly pink or light brown. When the level of Hb reaches 100 mg/dL, the plasma is red. When the level of plasma Hb reaches 150 mg/dL, hemoglobinuria occurs. In general, the quantity of the free Hb in the plasma correlates with the volume of incompatible blood transfused.

Fig. 49.13 Schematic representation of the effect on hemolyzed erythrocytes *(RBC)* due to the administration of incompatible blood.

Complement activation also causes release of various substances, including histamines and vasoactive amines. The symptoms can be so alarming that cessation of blood is indicated, even if Hb is not seen in plasma. Laboratory tests that should be performed if a hemolytic transfusion reaction is suspected include serum haptoglobin, plasma and urine Hb, bilirubin, and direct antiglobulin determinations. The direct antiglobulin test can confirm the presence of hemolytic transfusion reaction because it shows that antibody is attached to transfused donor RBCs.

Treatment

Although several consequences of intravascular hemolysis are possible, the renal and coagulation systems are affected the most. The cause of acute renal failure from intravascular hemolysis is likely due to precipitation of Hb in the form of acid hematin in the distal tubule causing mechanical tubular blockage. The magnitude of the precipitation probably is inversely related to the pH and volume of urine flow. Therapy should be directed toward maintaining urinary output in excess of 75 mL/h by generous administration of intravenous fluids and diuretics. One approach is summarized in Box 49.6 and includes the administration of crystalloids to maintain adequate intravascular volume while initially administering mannitol. If this is ineffective, the dose of mannitol may be increased or the use of more potent diuretics, such as furosemide may be required to maintain adequate urinary output. Alkalization of the urine to prevent precipitation of acid hematin in the distal tubules is of questionable value but is easy and therefore recommended. DIC commonly occurs with hemolytic transfusion reactions, probably because RBC stroma is severed, releasing erythrocytin, which activates the intrinsic system of coagulation and leads to fibrin formation. Subsequently, platelets and factors I, II, V, and VII are consumed. As soon as a hemolytic transfusion reaction is recognized, platelet count, PT, and PTT should be obtained to provide baseline values with which subsequent laboratory values can be compared. Hypotension during a hemolytic transfusion reaction may result from activation of the kallikrein system.[247]

BOX 49.6 Steps in the Treatment of a Hemolytic Transfusion Reaction

1. Stop the transfusion.
2. Maintain the urine output at a minimum of 75-100 mL/h by the following methods:
   a. Administer fluids intravenously and possibly mannitol
   b. Administer furosemide if intravenous fluids and mannitol are ineffective
3. Alkalinize the urine
4. Assay urine and plasma hemoglobin concentrations.
5. Determine platelet count, prothrombin time, partial thromboplastin time, and serum fibrinogen level.
6. Return unused blood to blood bank for repeat crossmatch.
7. Send patient's blood and urine sample to blood bank for examination.
8. Prevent hypotension to ensure adequate renal blood flow.

DELAYED HEMOLYTIC TRANSFUSION REACTION (IMMUNE EXTRAVASCULAR REACTION)

An immediate hemolytic transfusion reaction often is a dramatic event because the concentration of the antibody is high enough to cause immediate and appreciable RBC destruction. In many cases of hemolytic transfusion reaction, the transfused donor cells may survive initially, but after a variable delay (2-21 days), they are hemolyzed.[248] This type of reaction occurs mainly in recipients sensitized to RBC antigens by previous blood transfusions or pregnancy. As a result, this delayed reaction is more common in females with a known disposition for alloimmunization. These delayed hemolytic transfusion reactions occur when the level of antibody at the time of transfusion is too low to be detected. RBC destruction occurs only when the level of antibody is increased after a secondary stimulus (i.e., anamnestic response). These delayed reactions are often manifested only by a decrease in the posttransfusion Hct. Jaundice and hemoglobinuria can occur in these patients and can cause some impairment in renal function, but only rarely do they lead to death. Unlike immediate reactions, antibodies most commonly involved in delayed hemolytic reactions are those in the Rh and Kidd systems rather than the ABO system. Although improved blood-banking procedures have decreased the incidence of immediate hemolytic transfusion reactions, the delayed hemolytic reaction may not be preventable, because pretransfusion testing is unable to detect very low levels of antibody present in potential blood recipients.

The surgical team should include in their differential diagnosis a delayed hemolytic transfusion reaction in any patient who has an unexplained decrease in Hb 2 to 21 days after a transfusion, even without obvious manifestation of hemolysis. This is especially important in a postoperative patient when the decrease in Hb may be attributed to postoperative bleeding and lead to a return to the operative room for additional surgery.

TRANSFUSION-RELATED ACUTE LUNG INJURY

When a blood transfusion is implicated as the cause of ARDS, it is classified as TRALI. From 2012 to 2016, TRALI was the most common cause of transfusion-related mortality reported to the FDA[118] (see Table 49.8). Although it is underdiagnosed and underreported,[249-251] the incidence of TRALI varies from 1.3% to 3%, depending on the surgical procedures. In addition, larger transfused blood volumes appear to be associated with an increased incidence.[252] TRALI occurs in the absence of excessive intravascular volume and cardiac failure[253] and manifests as noncardiogenic pulmonary edema. Symptoms and signs usually appear within 6 hours after transfusion with a clear temporal relationship to the transfusion.[249] Fever, dyspnea, fluid in the endotracheal tube, and severe hypoxia are typical. During anesthesia, a persistent decrease of oxygen saturation can herald its insidious onset. Although the chest radiograph reveals pulmonary edema, excessive circulatory volume (i.e., left atrial hypertension) is not present. All blood components, especially FFP, are implicated as inciting factors. The only specific therapy is to stop the transfusion and institute supportive measures. The blood bank should be notified to provide blood components from a different donor and to quarantine all units from the donor in question. All records should be reexamined, and the results of the patient's HLA testing should be evaluated if possible. Although most patients recover within 96 hours, TRALI remains the leading cause of transfusion-related death.

Identified risk factors include higher interleukin-8 (IL-8) levels, liver surgery, chronic alcohol abuse, shock, higher peak airway pressures while being mechanically ventilated, smoking, and positive fluid-balance.[254] As far as blood products are concerned, receipt of plasma or whole blood from female donors, especially multiparous donors, was identified as the most common risk factor. The decreased use of plasma from female donors has markedly reduced the incidence of TRALI.

TRANSFUSION ASSOCIATED CIRCULATORY OVERLOAD

Unlike TRALI, TACO refers to an excessive administration volume of blood leading to pulmonary edema with evidence for increased left-sided cardiac filling pressures (e.g., elevated B-type natriuretic peptide/protein, elevated central venous pressure, new or worse left heart failure). TRALI and TACO have overlapping clinical findings and can be easily confounded (Table 49.17). In 2016 the FDA noted an increase in the case fatalities attributable to TACO, perhaps as a result of the increased reporting and improved understanding of the two entities.[118]

Recently, a retrospective analysis demonstrated a decreasing incident rate—with a rate of 5.5% in 2004 and 3% in 2011.[254a] Reasons for the decline are unclear but may be related to a more restrictive transfusion practice, thus limiting the exposure of a patient to potential volume overload; although this latter statement is purely conjecture and not supported by the findings of Clifford and associates. Besides volume transfused, other risk factors included advancing age and intraoperative fluid balance. Interestingly, leukoreduction may play a role in the reduced incidence of TACO, suggesting additional mechanisms of this entity's pathophysiology.[255] Diuretics may be helpful, but in both cases supportive measures such as lung protective ventilation should be instituted.

TABLE 49.17 Comparison of definitions of TACO and TRALI per CDC Guidelines.

TACO	TRALI
New onset or exacerbation of 3 or more of the following within 6 h of cessation of transfusion: ▪ Acute respiratory distress (dyspnea, cough, orthopnea) ▪ Elevated brain natriuretic peptide (BNP) ▪ Elevated central venous pressure (CVP) ▪ Evidence of left heart failure ▪ Evidence of positive fluid balance ▪ Radiographic evidence of pulmonary edema	No evidence of acute lung injury prior to transfusion AND ALI onset during or within 6 h of cessation of transfusion AND Hypoxemia defined by any of these methods ▪ PaO2/FiO2 less than or equal to 300 mm Hg ▪ Oxygen saturation less than 90% on room air ▪ Other clinical evidence AND Radiographic evidence of bilateral infiltrates without evidence of left atrial hypertension (i.e., circulatory overload)

Adapted from the CDC, National Healthcare Safety Network Biovigilance Component. Hemovigilance Surveillance Protocol v2.5.2. April 2018.

NONHEMOLYTIC TRANSFUSION REACTIONS

Nonhemolytic reactions to blood transfusions usually are not serious and are categorized into febrile or allergic. The most common adverse reactions to blood transfusions are febrile reactions. The symptoms consist of chills, fever, headache, myalgia, nausea, and nonproductive cough occurring shortly after a blood transfusion and are caused by pyrogenic cytokines and intracellular contents released by donor leukocytes. Use of leukoreduced blood has lowered the incidence of febrile reactions.[256] Less frequently, the patient may have other symptoms such as hypotension, chest pain, vomiting, and dyspnea. Even pulmonary infiltrations with radiographic evidence of prehilar nodule formation and lower lung infiltrates along with overt pulmonary edema have been reported.[256] A direct antiglobulin test readily differentiates a hemolytic reaction from a febrile reaction because this test rules out the attachment of antibody to transfused donor RBCs. More serious complications may need to be ruled out (e.g., hemolytic or septic reactions), which may also be associated with fever and chills. No clear consensus exists on whether the transfusion should be terminated when a febrile reaction occurs.[257,258]

Allergic reactions can be minor, anaphylactoid, or anaphylactic. An anaphylactoid reaction is clinically similar to anaphylaxis, but it is not mediated by IgE. Most allergic transfusion reactions are minor and caused by the presence of foreign protein in the transfused blood. The most common symptom is urticaria associated with itching. Occasionally, the patient has facial swelling. The transfusion usually does not need to be discontinued. Antihistamines are used to relieve the symptoms of the allergic reaction. Infrequently, a more severe form of allergic reaction involving anaphylaxis occurs in which the patient has dyspnea, hypotension, laryngeal edema, chest pain, and shock. These are anaphylactic reactions caused by the transfusion of IgA to patients who are IgA deficient and have formed anti-IgA. This type of reaction does not involve red cell destruction and occurs very rapidly, usually after the transfusion of only a few milliliters of blood or plasma. Patients who experience anaphylactic reactions should be given transfusions with washed RBCs so that all traces of donor IgA have been removed or with blood that lacks the IgA protein.

OTHER ADVERSE EFFECTS OF BLOOD TRANSFUSION

Transfusion-Associated Graft-Versus-Host Disease

Transfusion-associated graft-versus-host disease (GVHD) is caused by engraftment of donor lymphocytes from transfused blood products, initiating an immune reaction against recipient tissues. Severely immunocompromised patients are at risk. Also, directed donations from first- or second-degree relatives are at risk because transfused lymphocytes with shared HLA haplotypes cannot be recognized and eliminated.[259] A generalized rash, leukopenia, and thrombocytopenia occur. Sepsis and death usually result. Irradiation of blood can prevent transfusion-associated GVHD from occurring, although one case reported it occurring despite leukocyte filtering.[260]

Transfusion-Related Immunomodulation

Homologous (allogeneic) blood transfusion exerts a nonspecific immunosuppressive action on the recipient. More than 150 clinical studies have tried to relate allogeneic blood transfusions to recurrence of resected cancers, postoperative infections, and virus activation, with the conclusion that adverse effects may be caused by transfusion-related immunomodulation. Although the conclusions of these studies are contradictory and inconclusive, universal leukocyte reduction of RBCs is moving forward.[261,262]

OTHER NONINFECTIOUS RISKS OF BLOOD TRANSFUSIONS

Table 49.18 lists some of the less common noninfectious risks of blood transfusions.

1. Microchimerism: Chimerism refers to more than one cell line in an individual organism. Specifically, donor lymphocytes may persist in a patient. The outcome of patients with microchimerism is not known.
2. Posttransfusion purpura: This refers to recipient alloantibodies attacking donor platelet antigens and is treated with intravenous immunoglobulin.
3. Hypotensive transfusion reactions: Activation of the coagulation pathway activates production of bradykinin and allergic reactions.
4. Transfusion-related AKI.
5. Alloimmunization: Only 2% to 8% of recipients who are chronically transfused develop RBC alloantibodies.[5]
6. HLA alloimmunization and human platelet antigen (HPA) alloimmunization: HLA alloimmunization refers to patients whose platelet counts become refractory to transfusions because of antibodies directed against HLA class I antibodies. HPA alloimmunization is platelet refractoriness from antibodies against platelet antigens (HPA antibodies).
7. Iron overload: This complication is the result of chronic transfusion therapy. Iron begins to deposit into vital organs. In the absence of adequate chelation of iron, fatal liver or heart dysfunction, or both, can occur.
8. Adverse ocular reaction: In 1997, 112 cases of bilateral conjunctival erythema occurred within 24 hours of transfusion. The Centers for Disease Control and Prevention (CDC) studied 49 other cases in 1997 and 1998 and concluded that they were toxic reactions to a chemical or material used in the blood collection filtration system, most likely a leukocyte-reducing filter system.[263]

Leukoreduction and Irradiation of Blood Transfusions

GENERAL CONSIDERATIONS

Universal leukoreduction has been implemented because of some anticipated benefits. The chances of a febrile reaction can be reduced, especially in patients who are already alloimmunized from pregnancy. The risk for HLA alloimmunization from blood transfusions can be reduced, minimizing refractoriness to platelet transfusions, and the risk for CMV can be reduced. Leukoreduction can also decrease transmission of variant Creutzfeldt-Jakob disease, leukocyte-induced immunomodulation, and even postoperative mortality. In 2001, the case for and against universal leukoreduction was debated.[264,265] As of 2004, these anticipated benefits were not confirmed, despite numerous studies attempting to do so,[266] but a “may help, won’t hurt” approach has been used to justify universal leukoreduction.[264]

IRRADIATED BLOOD PRODUCTS

Blood products are irradiated to prevent the proliferation of donor T lymphocytes in blood, which are the immediate cause of transfusion-associated GVHD.[267] Fewer than one per million transfusions result in transfusion-associated GVHD, but this disease has a fatality rate greater than 90%. Only cellular products (RBCs, platelets, and granulocytes), but not noncellular products (thawed frozen plasma and cryoprecipitate), need be irradiated. Indications for irradiation include:

1. Fetal recipients of intrauterine transfusions
2. Infants younger than 4 months of age
3. Critically ill children
4. Children younger than 1 year of age undergoing extracorporeal membrane oxygenation/extracorporeal cardiac life support
5. Recipients of cellular components known to be from a blood relative
6. Recipients of cellular components whose donor is selected for HLA compatibility
7. Recipients who have undergone marrow or peripheral blood progenitor cell transplantation

TABLE 49.18 Noninfectious Hazards of Transfusion

Transfusion Reaction	Incidence (per 10^5 Transfusions)	Etiology	Therapy	Prevention
Febrile	All components: 70-6800	Storage-generated proinflammatory cytokines Patient antileukocyte antibodies bind to donor leukocytes	Stop transfusing Give antipyretics Supportive care	Prestorage leukoreduction
TACO	All components: 16.8-8000 Practice-dependent	Circulatory overload Patients with cardiac or renal disease, infants, and the critically ill are at increased risk	Stop transfusing Give diuretics Oxygen	Identify patients at high risk Transfuse slowly
TRALI	Erythrocytes: 10-20 Platelets/plasma: 50-100	Passive transfusion of donor antibodies Storage-generated toxic lipids	Supportive care	Remove high-risk donors from the donor pool
Allergic	All components: 3000 mild, 2 anaphylactic	Mild reactions: Transfusion of soluble antigens in donor plasma Anaphylaxis: IgA deficiency or other recipient protein deficiency	Stop transfusing ASA monitors Large-bore IV access Epinephrine Antihistamines Supportive care	Pretransfusion antihistamine use remains common practice despite limited evidence
Hemolytic	Erythrocytes: 1.1-9.0	Donor antibodies bind to patient erythrocytes Patient antibodies bind to donor erythrocytes	Stop transfusing Repeat matching Supportive care Treat DIC	Standard operating procedures
TRIM	Unknown	The mechanism is unknown but may depend on the presence of donor leukocytes	Treat complications (e.g., infection, malignancy)	Prestorage leukocyte reduction may be beneficial, but this approach is controversial
Microchimerism	All components: 5000-10,000 massive transfusion	Permanent residence of donor cells in recipient	Unknown	Unknown
Posttransfusion purpura	All components: 2	Recipient alloantibodies attack donor platelet antigens	IVIG	Avoid units positive for implicated HPA antigens in patients with a history of PTP
Hypotensive	Unknown	Production of kinins by the activation of the contact system Patients on ACE inhibitors are at increased risk	Stop transfusing ASA monitors Large-bore IV access Supportive care	Avoid the use of negatively charged leukocyte reduction filters
Graft-versus-host	Varies by patient population	Transfusion into immunocompromised host Transfusion of donor cells closely matching HLA type	No consensus exists Consider bone marrow transplant	Gamma irradiation of cellular products

Irradiation is not necessary for patients undergoing routine nonmyeloablative chemotherapy for solid tumors and solid organ transplant patients receiving routine posttransplant immunosuppressive therapy.

Informed Consent

Before any transfusion is given, informed consent should be obtained from the patient or guardian. What constitutes consent varies across the United States and is still changing. If a patient is injured by a transfusion administered without a valid consent, damages may be recovered even though the defendant did everything properly.[146] Many years ago, the *Paul Gann Blood Safety Act* was passed in California. This law mandated that patients be informed of the risks of blood transfusions and of any alternatives. The changes in transfusion medicine should lead to additional education for clinicians who administer blood products to ensure they are compliant with current laws and regulations. Local hospital transfusion medicine committees can provide clinicians with such information.

Acknowledgment

This chapter incorporates portions of the 8th edition Chapter 63, "Patient Blood Management: Autologous Blood Procurement, Recombinant Factor VIIa Therapy, and Blood Utilization." The editors and publisher would like to thank Drs. Lawrence T. Goodnough and Terri Monk for contributing content on this topic in the prior edition of this work.

50 Patient Blood Management: Coagulation

ANIL K. PANIGRAHI and LINDA L. LIU

KEY POINTS

- Normal hemostasis is a balance between generation of a localized hemostatic clot and uncontrolled thrombus formation.
- The extrinsic pathway of coagulation begins with exposure of blood plasma to tissue factor and represents the initiation phase of plasma-mediated hemostasis.
- The intrinsic pathway amplifies and propagates the hemostatic response to maximize thrombin generation.
- The common pathway generates thrombin, forms fibrin, and crosslinks fibrin strands to produce an insoluble fibrin clot.
- Routine preoperative coagulation testing of all surgical patients is costly and lacks predictive value for detection of hemostatic abnormalities. Testing should be based on the preoperative history and physical examination and the planned surgery.
- Antiplatelet agents and anticoagulants are used to reduce the formation of blood clots in the setting of coronary or cerebral atherosclerosis or after vascular thrombosis.
- Thrombolytic therapy is used to break up or dissolve blood clots.
- Procoagulant drugs (antifibrinolytics, factor replacements, prothrombin complex concentrate) help control blood loss during surgery.
- Perioperative management of patients who require chronic anticoagulation or antiplatelet therapy involves balancing the risk of surgical bleeding against the risk of developing postoperative thromboembolism.

Introduction

Hemostasis is an ordered enzymatic process involving cellular and biochemical components that function to preserve the integrity of the circulatory system after injury. The ultimate goal of this process is to limit blood loss secondary to vascular injury, maintain intravascular blood flow, and promote revascularization after thrombosis. As such, normal physiologic hemostasis is a constant balance between procoagulant pathways responsible for generation of a stable localized hemostatic clot and counter-regulatory mechanisms inhibiting uncontrolled thrombus propagation or premature thrombus degradation. Vascular endothelium, platelets, and plasma coagulation proteins play equally important roles in this process. Derangements in this delicate system can lead to excessive bleeding or pathologic thrombus formation. This chapter will examine normal and abnormal hemostasis, mechanisms to monitor coagulation, medications to manipulate coagulation, and management options for the perioperative anticoagulated patient.

Normal Hemostasis

Vascular endothelial injury—mechanical or biochemical—leads to platelet deposition at the injury site, a process often referred to as primary hemostasis. Although this initial platelet plug may prove adequate for a minor injury, control of more significant bleeding necessitates stable clot formation incorporating crosslinked fibrin—a process mediated by activation of plasma clotting factors and often referred to as secondary hemostasis. Although the terms primary and secondary hemostasis remain relevant for descriptive and diagnostic purposes, advances in understanding cellular and molecular processes underlying hemostasis suggest a far more complex interplay between vascular endothelium, platelets, and plasma-mediated hemostasis than is reflected in this model.[1]

VASCULAR ENDOTHELIAL ROLE IN HEMOSTASIS

In order to maintain blood flow throughout the circulatory system, the vascular endothelium employs several strategies to inhibit unprovoked thrombus formation. Healthy endothelial cells possess antiplatelet, anticoagulant, and profibrinolytic effects to inhibit clot formation.[2] The negatively charged vascular endothelium repels platelets, and endothelial cells produce potent platelet inhibitors such as prostacyclin (prostaglandin I_2,) and nitric oxide (NO).[3,4] An adenosine diphosphatase (CD39) expressed on the surface of vascular endothelial cells also serves to block platelet activation via degradation of adenosine diphosphate (ADP), a potent platelet activator.[5] Given these endogenous antiplatelet effects, quiescent platelets normally do not adhere to healthy vascular endothelial cells.

The vascular endothelium also plays a pivotal anticoagulant role through expression of several inhibitors of plasma-mediated hemostasis. Endothelial cells increase activation of protein C, an anticoagulant, via surface glycoprotein thrombomodulin (TM), which acts as a cofactor for thrombin-mediated activation of protein C, making its activation 1000 times faster. Endothelial cells also increase endothelial cell protein C receptor, which further enhances protein C activation by an additional 20-fold.[6] Endothelial-bound glycosaminoglycans, such as heparan sulfate, function to accelerate the protease activity of antithrombin (AT), which degrades factors IXa, Xa, and thrombin.[7] Endothelial cells also produce tissue factor pathway inhibitor (TFPI), which inhibits the procoagulant activity of factor Xa as well as the TF-VIIa complex.[8] Finally, the vascular endothelium synthesizes tissue plasminogen activator (t-PA), which is responsible for activating fibrinolysis, a primary counter-regulatory mechanism limiting clot propagation.

Despite these natural defense mechanisms to inhibit thrombus generation, a variety of mechanical and chemical stimuli may shift the balance such that the endothelium instead promotes clot formation. Damage to vascular endothelial cells exposes the underlying extracellular matrix (ECM), which contains collagen, von Willebrand factor (vWF), and other platelet-adhesive glycoproteins.[9,10] Platelets bind to and are activated by exposure to ECM components. Exposure of tissue factor, constitutively expressed by fibroblasts in the ECM, activates plasma-mediated coagulation pathways to generate thrombin and fibrin clot.[11] Certain cytokines (i.e., interleukin-1, tumor necrosis factor, and γ-interferon) and hormones (i.e., desmopressin acetate [DDAVP] or endotoxin) induce prothrombotic changes in vascular endothelial cells by increasing synthesis and expression of vWF, tissue factor, and plasminogen activator inhibitor-1 (PAI-1), and down-regulating normal antithrombotic cellular and biochemical pathways.[12,13] Finally, thrombin, hypoxia, and high fluid shear stress can also induce prothrombotic vascular endothelial changes such as increased synthesis of PAI-1. This associated inhibition of fibrinolysis has been implicated in the prothrombotic state and high incidence of venous thrombosis after surgery.[14,15]

PLATELETS AND HEMOSTASIS

Platelets contribute a critical role in hemostasis. Derived from bone marrow megakaryocytes, nonactivated platelets circulate as discoid anuclear cells with a lifespan of 8 to 12 days.[16] Under normal conditions, approximately 10% of platelets are consumed to support vascular integrity with $1.2-1.5 \times 10^{11}$ new platelets formed daily.[17] The platelet membrane is characterized by numerous receptors and a surface-connected open canalicular system serving to increase platelet membrane surface area and provide rapid communication between the platelet interior and exterior environment.[18] Under normal circumstances, platelets do not bind the vascular endothelium. However, when injury occurs, platelets contribute to hemostasis by adhering to the damaged vasculature, aggregating with one another to form a platelet plug, and facilitating generation of fibrin crosslinks to stabilize and reinforce the plug. Initially, upon exposure of the ECM, platelets undergo a series of biochemical and physical alterations characterized by three major phases: adhesion, activation, and aggregation. Exposure of subendothelial matrix proteins (i.e., collagen, vWF, fibronectin) allows for platelet adhesion to the vascular wall. vWF proves particularly important as a bridging molecule between ECM collagen and platelet glycoprotein Ib/factor IX/factor V receptor complexes.[19] Absence of either von Willebrand disease (vWF) or glycoprotein Ib/factor IX/factor V receptors (Bernard-Soulier syndrome) results in a clinically significant bleeding disorder.

In addition to promoting their adhesion to the vessel wall, the platelet interaction with collagen serves as a potent stimulus for the subsequent phase of thrombus formation, termed platelet activation. The generation of thrombin resulting from exposure of tissue factor, functions as a second pathway for platelet activation. Platelets contain two specific types of storage granules: α granules and dense bodies.[18] α granules contain numerous proteins essential to hemostasis and wound repair, including fibrinogen, coagulation factors V and VIII, vWF, platelet-derived growth factor, and others. Dense bodies contain the adenine nucleotides ADP and adenosine triphosphate, as well as calcium, serotonin, histamine, and epinephrine. During the activation phase, platelets release granular contents, resulting in recruitment and activation of additional platelets and propagation of plasma-mediated coagulation.[20] During activation, platelets undergo structural changes to develop pseudopod-like membrane extensions and to release physiologically active microparticles, which serve to dramatically increase platelet membrane surface area. Redistribution of platelet membrane phospholipids during activation exposes newly activated glycoprotein platelet surface receptors and phospholipid binding sites for calcium and coagulation factor activation complexes, which is critical to propagation of plasma-mediated hemostasis.[1]

During the final phase of platelet aggregation, activators released during the activation phase recruit additional platelets to the site of injury. Newly active glycoprotein IIb/IIIa receptors on the platelet surface bind fibrinogen, thereby promoting cross-linking and aggregation with adjacent platelets.[20] The importance of these receptors is reflected by the bleeding disorder associated with their hereditary deficiency, Glanzmann thrombasthenia.

PLASMA-MEDIATED HEMOSTASIS

Plasma-mediated hemostasis was originally described as a cascade or waterfall sequence of steps involving the serial activation of enzymes and cofactors to accelerate and amplify fibrin generation by thrombin.[21] Trace plasma proteins, activated by exposure to tissue factor or foreign surfaces, initiate this series of reactions culminating in conversion of soluble fibrinogen to insoluble fibrin clot.[22] Thrombin generation, the "thrombin burst," represents the key regulatory step in this process. Thrombin not only generates fibrin but also activates platelets and mediates a host of additional processes affecting inflammation, mitogenesis, and even down-regulation of hemostasis.[23]

Traditionally, the coagulation cascade describing plasma-mediated hemostasis has been depicted as extrinsic and intrinsic pathways, both of which culminate in a common pathway in which fibrin generation occurs.[24] This cascade model has proven to be an oversimplification,

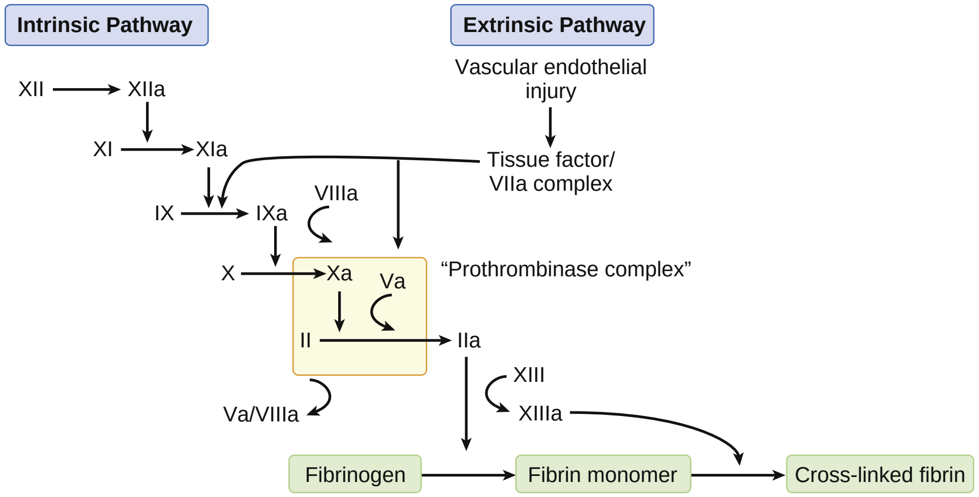

Fig. 50.1 Depiction of the Classic Coagulation Cascade Incorporating Extrinsic and Intrinsic Pathways of Coagulation. (From Slaughter TF. The coagulation system and cardiac surgery. In: Estafanous FG, Barasch PG, Reves JG, eds. *Cardiac Anesthesia: Principles and Clinical Practice.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2001: 320, with permission.)

as it does not fully reflect in vivo hemostasis. For instance, individuals with deficiencies in the intrinsic pathway (factor XII, prekallikrein, or high molecular weight kininogen) exhibit prolongations of the activated partial thromboplastin time (aPTT), but do not actually experience an increased bleeding risk. Nevertheless, the cascade model remains a useful descriptive tool for organizing discussions of plasma-mediated hemostasis (Fig. 50.1). Coagulation factors are, for the most part, synthesized by the liver and circulate as inactive proteins termed zymogens. The somewhat confusing nomenclature of the classic coagulation cascade derives from the fact that inactive zymogens were identified using Roman numerals assigned in order of discovery. As the zymogen is converted to an active enzyme, a lower-case letter "a" is added to the Roman numeral identifier. For example, inactive prothrombin is referred to as factor II and active thrombin is identified as factor IIa. Some numerals were subsequently withdrawn or renamed as our understanding of the coagulation pathway evolved.

The cascade characterizes a series of enzymatic reactions in which inactive precursors—zymogens—undergo activation to amplify the overall reaction. Each stage of the cascade requires assembly of membrane-bound activation complexes, each composed of an enzyme (activated coagulation factor), substrate (inactive precursor zymogen), cofactor (accelerator or catalyst), and calcium.[25] Assembly of these activation complexes occurs on platelet or microparticle phospholipid membranes that localize and concentrate reactants. Coagulation factor activation slows dramatically in the absence of these phospholipid membrane anchoring sites. This requirement functionally confines clot formation to sites of injury.

Extrinsic Pathway of Coagulation

The extrinsic pathway of coagulation is now understood to represent the initiation phase of plasma-mediated hemostasis and begins with exposure of blood plasma to tissue factor.[26] Tissue factor is prevalent in subendothelial tissues surrounding the vasculature. Under normal conditions, the vascular endothelium minimizes contact between tissue factor and plasma coagulation factors. After vascular injury, small concentrations of factor VIIa circulating in plasma form phospholipid-bound activation complexes with tissue factor, factor X, and calcium to promote conversion of factor X to Xa.[22] Additionally, the tissue factor/factor VIIa complex also activates factor IX of the intrinsic pathway, further demonstrating the key role of tissue factor in initiating hemostasis.[27]

Intrinsic Pathway of Coagulation

Classically, the intrinsic or contact activation system was described as a parallel pathway for thrombin generation initiated by factor XII activation after contact with negatively charged surfaces such as glass, dextran sulfate, or kaolin. However, the rarity of bleeding disorders resulting from contact activation factor deficiencies led to our current understanding of the intrinsic pathway as an amplification system to propagate thrombin generation initiated by the extrinsic pathway.[28] Recent cell-based models of coagulation suggest that thrombin generation by way of the extrinsic pathway is limited by a natural inhibitor, TFPI,[29] but the small quantities of thrombin generated do activate factor XI and the intrinsic pathway. The intrinsic pathway then subsequently amplifies and propagates the hemostatic response to maximize thrombin generation (Fig. 50.2). Although factor XII may be activated by foreign surfaces (i.e., cardiopulmonary bypass [CPB] circuits or glass vials), the intrinsic pathway plays a minor role in the initiation of hemostasis. Proteins of the intrinsic pathway may, however, contribute to inflammatory processes, complement activation, fibrinolysis, kinin generation, and angiogenesis.[28]

Common Pathway of Coagulation

The final pathway, common to both extrinsic and intrinsic coagulation cascades, depicts thrombin generation and subsequent fibrin formation. Signal amplification results from activation of factor X by both intrinsic (FIXa, FVIIIa, Ca^{2+}) and extrinsic (tissue factor, FVIIa, Ca^{2+}) tenase complexes. The tenase complexes in turn facilitate formation of the

Fig. 50.2 Clot Formation at Vascular Injury Site. Vascular injury exposes subendothelial tissue factor *(TF)* initiating plasma-mediated hemostasis via the extrinsic pathway. The intrinsic pathway further amplifies thrombin and fibrin generation. Platelets adhere to exposed collagen to undergo activation, resulting in recruitment and aggregation of additional platelets. (From Mackman N, Tilley RE, Key NS. Role of extrinsic pathway of blood coagulation in hemostasis and thrombosis. *Arterioscleros Thromb Vasc Biol.* 2007;27:1687–1693, with permission.)

prothrombinase complex (FXa, FII [prothrombin], FVa [cofactor], and Ca^{2+}), which mediates a surge in thrombin generation from prothrombin.[30] Thrombin proteolytically cleaves fibrinopeptides A and B from fibrinogen molecules to generate fibrin monomers, which polymerize into fibrin strands to form clot.[30] Finally, factor XIIIa, a transglutaminase activated by thrombin, covalently crosslinks fibrin strands to produce an insoluble fibrin clot resistant to fibrinolytic degradation.[31]

Both fibrinogen and factor XIII have been implicated in acquired bleeding disorders. Reduced concentrations of either protein may promote excess postoperative hemorrhage and transfusion requirements. Recent availability of plasma concentrates for both fibrinogen and factor XIII suggest the potential for randomized controlled trials to determine efficacy of these biologics in treatment of acquired coagulopathies.[32]

Thrombin generation remains the key enzymatic step regulating hemostasis. Not only does thrombin activity mediate conversion of fibrinogen to fibrin, but it also has a host of other actions. It activates platelets and factor XIII, converts inactive cofactors V and VIII to active conformations, activates factor XI and the intrinsic pathway, up-regulates expression of tissue factor, stimulates vascular endothelial expression of PAI-1 to down-regulate fibrinolytic activity, and suppresses uncontrolled thrombosis through activation of protein C.[33]

Intrinsic Anticoagulant Mechanisms

Once activated, regulation of hemostasis proves essential to limit clot propagation beyond the injury site. One simple, yet important, anticoagulant mechanism derives from flowing blood and hemodilution. The early platelet and fibrin clot proves highly susceptible to disruption by shear forces from flowing blood. Blood flow further limits localization and concentration of both platelets and coagulation factors such that a critical mass of hemostatic components may fail to coalesce.[30,34] However, later in the clotting process, more robust counter-regulatory mechanisms are necessary to limit clot propagation. Four major counter-regulatory pathways have been identified that appear particularly crucial for down-regulating hemostasis: fibrinolysis, TFPI, the protein C system, and serine protease inhibitors (SERPINs).

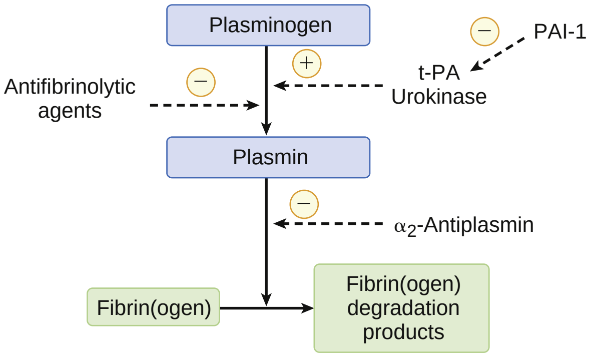

Fig. 50.3 Principal Mediators of Fibrinolysis. Dashed lines depict sites of action for promoters and inhibitors of fibrinolysis. *PAI,* Plasminogen activator inhibitor; *tPA,* tissue plasminogen activator. (From Slaughter TF. Philadelphia: Lippincott Williams & Wilkins; 2001:320, with permission.)

The fibrinolytic system comprises a cascade of amplifying reactions culminating in plasmin generation and proteolytic degradation of fibrin and fibrinogen. As with the plasma-mediated coagulation cascade, inactive precursor proteins are converted to active enzymes, necessitating a balanced system of regulatory controls to prevent excessive bleeding or thrombosis (Fig. 50.3). The principal enzymatic mediator of fibrinolysis is the serine protease, plasmin, which is generated from plasminogen.[35] In vivo, plasmin generation is most often accomplished by release of t-PA or urokinase from the vascular endothelium. Activity of t-PA and urokinase is accelerated in the presence of fibrin, which limits fibrinolysis to areas of clot formation. Factor XIIa and kallikrein of the intrinsic pathway also contribute to fibrinolysis through activation of plasminogen after exposure to foreign surfaces.[36] Fortunately, fibrinolytic activity is limited by the rapid inhibition of free plasmin. In addition to enzymatic degradation of fibrin and fibrinogen, plasmin inhibits hemostasis by degrading essential cofactors V and VIII and reducing platelet glycoprotein surface receptors essential to adhesion and aggregation.[37] Fibrin degradation products also possess mild anticoagulant properties.

TFPI and factor Xa form phospholipid membrane-bound complexes that incorporate and inhibit tissue factor/factor VIIa complexes.[38] This inhibition leads to downregulation of the extrinsic coagulation pathway.[39] As TFPI rapidly extinguishes tissue factor/VIIa activity, the critical role of the intrinsic pathway to continued thrombin and fibrin generation becomes apparent.[28]

The protein C system proves particularly important in down-regulating coagulation through inhibition of thrombin and the essential cofactors Va and VIIIa. After binding to TM, thrombin's procoagulant function decreases and instead its ability to activate protein C is augmented.[40] Protein C, complexed with the cofactor protein S, degrades both cofactors Va and VIIIa. Loss of these critical cofactors limits formation of tenase and prothrombinase activation complexes essential to formation of factor Xa and thrombin, respectively. Additionally, once bound to TM, thrombin is rapidly inactivated and removed from circulation, providing another mechanism by which the protein C pathway down-regulates hemostasis.[40]

The most significant SERPINs regulating hemostasis include AT and heparin cofactor II. AT inhibits thrombin, as well as factors IXa, Xa, XIa, and XIIa. [41] Heparin binds AT causing a conformational change that accelerates AT-mediated inhibition of targeted enzymes. Heparin cofactor II is a more recently discovered SERPIN that inhibits thrombin alone.[42] Although the precise physiologic role for heparin cofactor II remains unclear, when bound by heparin, its inhibitory activity is dramatically increased.

Disorders of Hemostasis

EVALUATION OF BLEEDING DISORDERS

The perioperative period presents significant challenges to the hemostatic system; therefore, identification and correction of hemostatic disorders can be of vital importance. Unfortunately, assessment of bleeding risk continues to be a challenge and the optimal methods for preoperative evaluation remain controversial. Although routine preoperative coagulation testing of all surgical patients may seem prudent, such an approach is costly and lacks predictive value for detection of hemostatic abnormalities. Standard coagulation tests such as the prothrombin time (PT) and aPTT were designed as diagnostic tests to be used when a bleeding disorder is suspected based on clinical evaluation. As a result, when used as screening tests, these in vitro assays are limited in their ability to reflect the in vivo hemostatic response.[43] For example, because of the nature of establishing normal value ranges for these tests, 2.5% of healthy individuals will have abnormal PT or aPTT values. Meanwhile, those with mild hemophilia A, vWD, and factor XIII deficiency may experience clinically significant bleeding despite having normal values on standard testing.[44] Consequently, a carefully performed bleeding history remains the single most effective predictor of perioperative bleeding.

A thorough history should focus on prior bleeding episodes.[45] In particular, patients should be asked whether they have experienced excessive bleeding after hemostatic challenges such as dental extractions, surgery, trauma, or childbirth and whether blood transfusions or reoperation were required to control the bleeding. Common presentations suggestive of a bleeding disorder may include frequent epistaxis necessitating nasal packing or surgical intervention. Oral surgery and dental extractions prove particularly good tests of hemostasis because of increased fibrinolytic activity on the mucous membranes of the oral cavity. Women with platelet disorders or vWD may experience menorrhagia, and postpartum hemorrhage commonly occurs in those with underlying disorders of hemostasis.[46] A history of spontaneous nontraumatic hemorrhage proves particularly concerning when associated with hemarthroses or deep muscle bleeding. Identification of a bleeding disorder at an early age or in family members suggests an inherited condition. A careful medication history including direct questions relating to consumption of aspirin and nonsteroidal antiinflammatory drugs (NSAIDs), as well as supplements such as ginkgo and vitamin E.[47] Finally, inquiries regarding coexisting diseases should be included (i.e., renal, hepatic, thyroid, and bone marrow disorders and malignancy).

For most patients, a thoughtfully conducted bleeding history will eliminate the need for preoperative laboratory-based coagulation testing. Should the preoperative history or physical examination reveal signs or symptoms suggestive of a bleeding disorder, further laboratory testing is indicated. Preoperative coagulation screening tests may be indicated, despite a negative history, in cases in which the planned surgery is commonly associated with significant bleeding (i.e., CPB). Finally, preoperative testing may prove justified in settings in which the patient is unable to provide an adequate preoperative bleeding history. Should evidence of a bleeding disorder be detected, underlying etiologies should be clarified if possible before proceeding with surgery.

INHERITED BLEEDING DISORDERS

Von Willebrand Disease

Inherited disorders of hemostasis include those involving platelet quantity and function, coagulation factor deficiencies, or disorders of fibrinolytic pathways. Among these inherited bleeding disorders, vWD is the most common and is characterized by quantitative or qualitative deficiencies of vWF resulting in defective platelet adhesion and aggregation.[48] Affecting up to 1% of the population, vWD is categorized into three main types (types 1, 2, and 3). with most cases demonstrating an autosomal dominant inheritance pattern.[49] Types 1 and 3 lead to varying quantitative vWF deficiencies, while type 2 encompasses four subtypes expressing qualitative defects that affect vWF function. Under normal conditions, vWF plays a critical role in platelet adhesion to the ECM and prevents degradation of factor VIII by serving as a carrier molecule.[50] Classically, patients with vWD describe a history of easy bruising, recurrent epistaxis, and menorrhagia, which are characteristic of defects in platelet-mediated hemostasis. In more severe cases (i.e., type 3 vWD), concomitant reductions in factor VIII may lead to serious spontaneous hemorrhage, including hemarthroses.

Routine coagulation studies are generally not helpful in the diagnosis of vWD, as the platelet count and PT will be normal in most patients and the aPTT may demonstrate mild-to-moderate prolongation depending on the level of factor VIII reduction.[51] Instead, initial screening tests involve measurement of vWF levels (vWF antigen) and vWF platelet binding activity in the presence of the ristocetin cofactor, which leads to platelet agglutination. Measurable reductions in factor VIII activity may occur in severe cases.[52] Increasingly, platelet function tests have replaced bleeding times in assessing for vWD.[53,54] Mild cases of vWD often respond to DDAVP, which results in the release of vWF from endothelial cell. Use of vWF:factor VIII concentrates (Humate-P, CSL Behring, King of Prussia, PA) may be indicated in the perioperative period if there is a significant bleeding history.[55]

Hemophilias

Although less common than vWD, the hemophilias merit consideration given their diverse clinical presentation. Hemophilia A, factor VIII deficiency, and hemophilia B, factor IX deficiency, are both X-linked inherited bleeding disorders most frequently presenting in childhood as spontaneous hemorrhage involving joints, deep muscles, or both. Hemophilia A occurs with an incidence of 1:5000 males and hemophilia B in 1:30,000 males. While most cases are inherited, nearly one third of cases represent new mutations with no family history.[56] The severity of the disease depends on an individual's baseline factor activity level.[57] In mild cases, patients with hemophilia may not be identified until later in life, often after unexplained bleeding with surgery or trauma. Classically, laboratory testing in patients with hemophilia reveals prolongation of the aPTT, whereas the PT, bleeding time, and platelet count remain within normal limits. However, a normal aPTT may also be seen in mild forms of hemophilia; therefore, specific factor analyses need to be performed to confirm the diagnosis and determine the severity of the factor deficiency. In most cases, perioperative management of patients with hemophilia A or B necessitates consultation with a hematologist and administration of recombinant or purified factor VIII or factor IX concentrates, respectively.[58] Mild cases of hemophilia A may be treated with desmopressin. An increasingly common complication of hemophilia, particularly in the case of hemophilia A, has been the development of alloantibodies directed against the factor VIII protein.[59] Administration of factor VIII concentrates will fail to control bleeding in patients with high-titer antibodies. Several approaches to reduce bleeding in these patients include: substitution of porcine factor VIII, administration of activated (FEIBA, Shire Inc., Lexington, MA) or non-activated prothrombin complex concentrates (PCCs), or treatment with recombinant factor VIIa (NovoSeven, Novo Nordisk Inc., Bagsvaerd, Denmark).[60]

ACQUIRED BLEEDING DISORDERS

Drug Induced

Medications represent the most significant cause of acquired coagulopathy in perioperative patients. In addition to anticoagulants such as heparin and warfarin, the increasing number of direct oral anticoagulants(DOACs) and antiplatelet drugs have further complicated perioperative management. An understanding of the effect of these agents and strategies for reversal can be critical to reduce bleeding complications during urgent and emergent procedures. Additionally, there are several classes of medications that may unintentionally increase bleeding risk due to side effects, primarily via platelet inhibition. β-Lactam antibiotics impair platelet aggregation that can result in clinically significant bleeding in patients with higher baseline risk.[61] Nitroprusside,[62] nitroglycerin,[63] and NO[64] also result in decreased platelet aggregation and secretion. Similarly, selective-serotonin reuptake inhibitors, such as paroxetine, decrease platelet serotonin storage, which inhibits platelet aggregation and may have clinical consequences in individuals with preexisting coagulopathies.[65] These medications should be considered in patients with an otherwise unexplained coagulopathy.

Liver Disease

Hemostatic defects associated with hepatic failure prove complex and multifactorial. Severe liver disease impairs synthesis of coagulation factors, produces quantitative and qualitative platelet dysfunction, and impedes clearance of activated clotting and fibrinolytic proteins. The liver is the primary site for the production of procoagulant factors including fibrinogen, prothrombin (factor II), factors V, VII, IX, X, XI, XII, as well as the anticoagulants protein C and S, and AT. Laboratory findings commonly associated with liver disease include a prolonged PT and possible prolongation of the aPTT, suggesting that these individuals are at increased risk of bleeding. However, the abnormal values only reflect the decrease in procoagulant factors and do not account for the concomitant decrease in anticoagulant factors.[66] As a result, patients with chronic liver disease are thought to have a rebalanced hemostasis and actually generate amounts of thrombin equivalent to healthy individuals.[67]

Similarly, thrombocytopenia from splenic sequestration is often observed in patients with liver disease and portal hypertension[68] and is accompanied by platelet dysfunction due to increased production of endothelial NO and prostacyclin resulting in platelet inhibition.[69] Despite these alterations, increases in vWF commonly observed in these patients may serve to restore platelet function. Also, levels of the plasma metalloprotease ADAMTS13, responsible for cleaving vWF multimers, are decreased in chronic liver disease and result in high circulating levels of large vWF multimers that promote platelet aggregation.[70] This increase in vWF may in part correct for thrombocytopenia and platelet dysfunction but also can result in a prothrombotic state and increased clotting risk.

Fibrinolysis of formed clot is also aberrant in patients with liver disease. Normally, fibrin clot is degraded by plasmin, which is converted to its active form by t-PA and urokinase plasminogen activator (u-PA). Excessive fibrinolysis is prevented by thrombin-activatable fibrinolysis inhibitor (TAFI), which blocks activation of plasmin from plasminogen. TAFI is synthesized by the liver and as levels are decreased in patients with chronic liver disease, it was believed that such individuals are at increased bleeding risk due to hyperfibrinolysis.[71] However, levels of PAI-1, a SERPIN of t-PA and u-PA, are also increased in liver disease, which may in actuality normalize fibrinolysis.[72]

In summary, procoagulant and anticoagulant hemostatic mechanisms are rebalanced in patients with chronic liver disease, but this balance is easily disrupted and these patients are at risk for both bleeding and inappropriate clotting.[73] Traditional coagulation testing does not correlate with bleeding risk in these patients, which has led to studies looking at the use of viscoelastic coagulation testing using thromboelastography (TEG) or rotational thromboelastometry (ROTEM) as a means of assessing functional coagulation and guiding perioperative blood product transfusion and administration of antifibrinolytic agents.[73,74]

Renal Disease

Platelet dysfunction commonly occurs in association with chronic renal failure and uremia, as reflected by a prolonged bleeding time and propensity for bleeding associated with surgery or trauma. The underlying mechanisms are multifactorial but have mostly been attributed to decreased platelet aggregation and adhesion to injured vessel walls. Impaired adhesion is likely due to defects of the glycoprotein IIb/IIIa, which facilitates platelet binding of fibrinogen and vWF.[75,76] Additionally, accumulation of guanidinosuccinic acid and the resulting increase in endothelial NO synthesis further decreases platelet responsiveness.[77] Red blood cell (RBC) concentration has also been speculated to contribute to platelet dysfunction, as correction of anemia results in shortened bleeding times, presumably related to the role of RBCs in causing platelet margination along the vessel wall under laminar flow conditions.[78] Both dialysis and correction of anemia have been reported to shorten bleeding times in patients with chronic renal failure. Treatment of platelet dysfunction related to chronic renal disease includes transfusion of cryoprecipitate (rich in vWF) or administration of desmopressin (0.3 μg/kg), which stimulates release of vWF from endothelial cells.[79] Additionally, conjugated estrogens (0.6 mg/kg intravenously for 5 days) have been demonstrated to shorten bleeding times,[80] perhaps via decreased generation of NO.[81]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a pathologic hemostatic response to tissue factor/factor VIIa complex that leads to excessive activation of the extrinsic pathway, which overwhelms natural anticoagulant mechanisms and generates intravascular thrombin. Numerous underlying disorders may precipitate DIC, including trauma, amniotic fluid embolus, malignancy, sepsis, or incompatible blood transfusions.[82] Most often, DIC presents clinically as a diffuse bleeding disorder associated with consumption of coagulation factors and platelets during widespread microvascular thrombotic activity, which results in multiorgan dysfunction. Laboratory findings typical of DIC include reductions in platelet count; prolongation of the PT, aPTT, and thrombin time (TT); and elevated concentrations of soluble fibrin and fibrin degradation products. However, DIC is both a clinical and laboratory diagnosis; hence, laboratory data alone do not provide sufficient sensitivity or specificity to confirm a diagnosis.[83] For example, chronic DIC states have been identified with relatively normal screening coagulation tests accompanied by elevated concentrations of soluble fibrin and fibrin degradation products.[84] Management of DIC requires management of the underlying condition precipitating hemostatic activation. Otherwise, treatment is mostly supportive and includes selective blood component transfusions to replete coagulation factors and platelets consumed in the process. The use of anticoagulants such as heparin remains controversial with recommendations that its use be limited to conditions with the highest thrombotic risk.[85] Antifibrinolytic therapy generally is contraindicated in DIC, owing to the potential for catastrophic thrombotic complications.[86]

CARDIOPULMONARY BYPASS-ASSOCIATED COAGULOPATHY

Institution of CPB by directing blood flow through an extracorporeal circuit causes significant perturbations to the hemostatic system. Initial priming of the bypass circuit results in hemodilution and thrombocytopenia.[87] Adhesion of platelets to the synthetic surfaces of the bypass circuit further decreases platelet counts and contributes to platelet dysfunction.[88] During CPB, expression of platelet surface receptors important for adhesion and aggregation (GPIb, GPIIb/IIIa) are downregulated and the number of vWF-containing α granules are decreased, thereby impairing platelet function.[89] Furthermore, induced hypothermia during CPB results in reduced platelet aggregation and plasma-mediated coagulation by decreasing clotting factor production and enzymatic activity.[90] Hyperfibrinolysis may also occur as a result of CPB, supporting the use of antifibrinolytic drugs to decrease intraoperative blood loss.[91]

TRAUMA-INDUCED COAGULOPATHY

Uncontrolled hemorrhage is a frequent cause of trauma-related deaths. Coagulopathy in this setting may be due to acidosis, hypothermia, and hemodilution from resuscitation; however, an independent acute coagulopathy is also experienced by these individuals.[92] Termed trauma-induced coagulopathy (TIC) or acute traumatic coagulopathy, this process involves disordered hemostasis and increased fibrinolysis observed early after injury.[93] The anticoagulant effect of activated protein C (APC) is thought to play a primary role in TIC by decreasing thrombin generation via inhibition of factor Va and VIIIa and promoting fibrinolysis through inhibition of PAI-1. The relevance of APC in the development of TIC is supported by the association of hypoperfusion and increasing injury severity with increased levels of APC activity.[94] Hypoperfusion is thought to be the stimulus for APC activation.[95] Additionally, degradation of the endothelial glycocalyx (EG), a gel-like matrix lining the vascular endothelium, is linked to factors associated with trauma, including tissue damage, hypoperfusion, elevated catecholamines, and inflammation. The EG has anticoagulant properties and contains proteoglycans such as syndecan-1, hyaluronic acid, heparan sulfate, and chondroitin sulfate which are shed during endothelial injury. Shedding of proteoglycans results in an "autoheparinization" phenomenon that contributes to TIC. Markers of EG degradation have been found to be associated with inflammation, coagulopathy, and increased mortality in trauma patients.[96]

Although platelet counts appear to be normal, platelet dysfunction contributes to increased bleeding in TIC. Significant platelet hypofunction in response to various agonists, including ADP, arachidonic acid, and collagen, has

BOX 50.1 Hypercoagulable States and Risk for Perioperative Thrombosis

High Risk

- Heparin-induced thrombocytopenia
- Antithrombin deficiency
- Protein C deficiency
- Protein S deficiency
- Antiphospholipid antibody syndrome

Moderate Risk

- Factor V Leiden genetic polymorphism
- Prothrombin G20210A genetic polymorphism
- Hyperhomocysteinemia
- Dysfibrinogenemia
- Postoperative prothrombotic state
- Malignancy
- Immobilization

been observed acutely in trauma patients prior to resuscitation.[97,98] It is hypothesized that trauma patients experience "platelet exhaustion" as a result of activation from widespread release of ADP from injured tissues. This diffuse activation renders platelets unresponsive to subsequent stimulation.[98] Platelet insensitivity to ADP is also associated with increased susceptibility of clots to tPA-mediated fibrinolysis.[99] The importance of early treatment to reduce hyperfibrinolysis in trauma is supported by the findings of the Clinical Randomisation of an Antifibrinolytic in Significant Haemorrhage 2 (CRASH-2) trial, which demonstrated a mortality benefit from early administration of tranexamic acid (TXA).[100,101]

PROTHROMBOTIC STATES

Thrombophilia, a propensity for thrombotic events, commonly manifests clinically in the form of venous thrombosis (frequently deep venous thrombosis [DVT] of the lower extremity).[102] As with bleeding disorders, thrombophilia may result from inherited or acquired conditions (Box 50.1). The pathogenesis of thrombosis is thought to be due to Virchow's triad (blood stasis, endothelial injury, and hypercoagulability).[9] In the majority of cases, a risk factor or precipitating event is identified; however, a single factor generally does not result in clinically significant thrombosis.[103] Instead, multiple factors act synergistically to increase risk.[104] For example, thrombotic complications often occur after surgery or during pregnancy in association with obesity, underlying malignancy, or an inherited thrombophilia.[105] Random screening of asymptomatic patients for thrombotic risk has not proven cost effective or clinically efficacious.[106,107] As with bleeding disorders, a history focusing on prior thrombotic events, family history of thrombosis, and concurrent drug therapy offers greater predictive value than random screening.

INHERITED THROMBOTIC DISORDERS

Improvements in biochemical and molecular testing have dramatically improved our understanding of blood coagulation and the prevalence of prothrombotic disorders.[108] Because of more specific testing, an inheritable thrombotic predisposition is identified in as many as 50% of patients presenting with venous thromboembolism.[109] The most common inherited prothrombotic conditions include single point mutations in genes for factor V (factor V Leiden) or prothrombin (prothrombin G20210A). In the case of the factor V Leiden, the mutation results in APC resistance whereby the essential cofactor Va is no longer susceptible to APC-mediated degradation. This simple alteration in balance between hemostasis and the APC counter-regulatory system induces a prothrombotic condition present in approximately 5% of the Caucasian population.[110] In the case of the prothrombin gene mutation, increased prothrombin concentrations in plasma generate a hypercoagulable state. Less common inherited forms of thrombophilia include deficiencies of AT, protein C, or protein S.[108] Inherited forms of thrombophilia are characterized by highly variable penetrance affected by blood type, sex, and other confounding variables. Environmental factors such as oral contraceptive use, pregnancy, immobility, infection, surgery, or trauma greatly affect the incidence of thrombosis in those with an inherited predisposition.[111] In the absence of coexisting precipitating conditions, presence of a family history, test abnormality suggesting thrombophilia, or history of thrombosis, risks associated with long-term preventive anticoagulation may outweigh potential benefits.[106] After a thrombotic complication, however, these patients most often are managed with life-long anticoagulation.

ACQUIRED THROMBOTIC DISORDERS

Antiphospholipid Syndrome

Antiphospholipid syndrome (APS) describes an acquired autoimmune disorder characterized by venous or arterial thromboses, or both, and recurrent pregnancy loss. This syndrome may occur in association with autoimmune disorders such as systemic lupus erythematosus or rheumatoid arthritis, or it may occur in isolation. APS results from development of autoantibodies directed against phospholipid-binding proteins, which affect the coagulation system and is associated with up to 10% of cases of DVT and 6% of pregnancy-associated morbidity.[112] Characteristically, APS results in mild prolongation of the aPTT and positive testing for lupus anticoagulant, anticardiolipin or anti-β2-glycoprotein I antibodies.[113] Antibodies associated with APS interfere with phospholipids common to many laboratory-based tests of coagulation. Despite the prolonged aPTT, APS poses no increased bleeding risk but rather increases the potential for thrombosis. Isolated prolongation of an aPTT in a preoperative patient merits consideration of the diagnosis of APS. Patients with this syndrome who have experienced a thrombotic complication are at increased risk for recurrent thrombosis and most often are managed by life-long anticoagulation.[114]

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia (HIT) describes an autoimmune-mediated drug reaction occurring in as many as 5% of patients receiving heparin therapy. Patients with HIT experience a mild-to-moderate thrombocytopenia. As opposed to other drug-induced thrombocytopenias, HIT

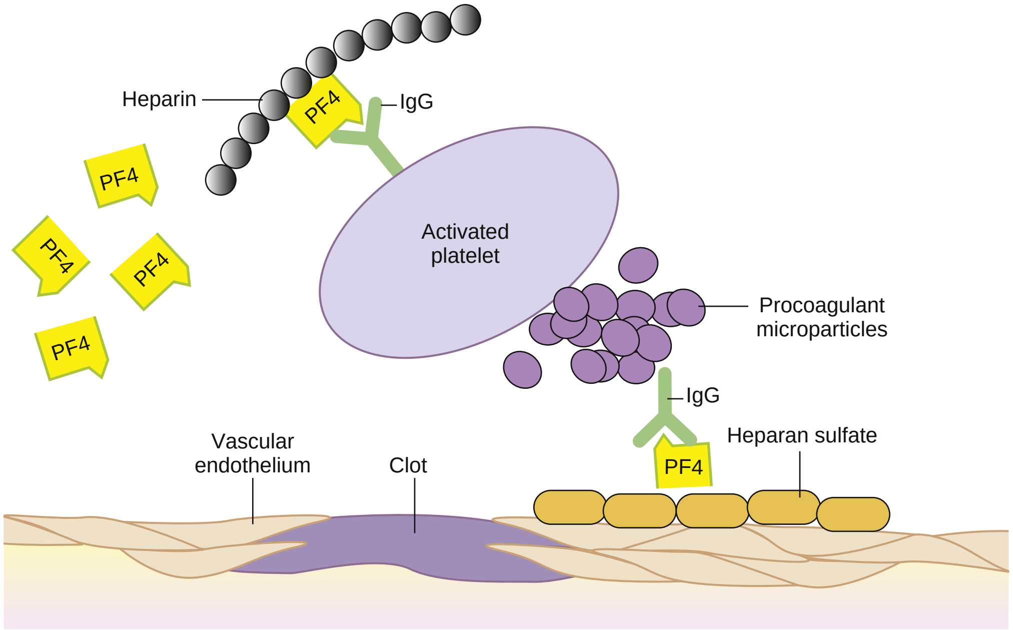

Fig. 50.4 Mechanisms Underlying Thrombosis in Heparin-Induced Thrombocytopenia. Immune complexes composed of heparin, platelet factor 4 *(PF4)*, and antibodies bind to platelet surface Fcγ receptors to activate platelets. PF4/heparin immune complexes further activate vascular endothelium, monocytes, and macrophages to increase tissue factor expression. *IgG,* Immunoglobulin G. (From Slaughter TF, Greenberg CS. Heparin-associated thrombocytopenia and thrombosis: Implications for perioperative management. *Anesthesiology*. 1997;87:669, with permission.)

results in platelet activation and potential for venous and arterial thromboses.[115] Evidence suggests that HIT is mediated by immune complexes (composed of immunoglobulin G [IgG] antibody, platelet factor 4 [PF4], and heparin) that bind platelet Fcγ receptors to activate platelets. Anti-PF4/heparin antibodies may "activate" vascular endothelium, monocytes, and macrophages by up-regulating tissue factor expression (Fig. 50.4). Risk factors for development of HIT include patient population, gender, and heparin formulation used. Women are at increased risk of HIT (odds ratio [OR] 2.37; 95% CI 1.37-4.09) as are surgical patients compared to medical patients (OR 3.25; 95% CI 1.98-5.35). [116] Given the high doses of heparin administered during cardiac surgery with CPB, these patients have a higher incidence of anti-PF4 antibody development (up to 50%); however, the incidence of HIT in this population appears to be similar to other surgical groups.[117] Use of unfractionated heparin (UFH) carries a greater risk of HIT development than low-molecular-weight heparin (LMWH) (absolute risk 2.6% vs. 0.2%).[118] Patients developing HIT during heparin therapy experience substantially increased risk for thrombosis (OR 20:40, absolute risk 30% to 75%).[115]

HIT manifests clinically as thrombocytopenia occurring 5 to 14 days after initiating heparin therapy. With prior heparin exposure, thrombocytopenia or thrombosis may occur within 1 day. A diagnosis of HIT should be entertained for any patient experiencing thrombosis or thrombocytopenia (absolute or relative ≥ 50% reduction in platelet count) during or after heparin administration. Although HIT remains a clinical diagnosis, HIT antibodies testing should be undertaken to confirm the diagnosis. The enzyme-linked immunosorbent assay (ELISA) is sensitive, but not as specific as the serotonin release assay (SRA), because the SRA indicates heparin-induced platelet activation. For many intensive care patients, a positive ELISA test does not lead to a positive SRA, which means these patients are unlikely to have HIT.[119]

In cases where HIT is suspected, heparin must be discontinued immediately (including UFH, LMWH, heparin-bonded catheters, heparin flushes). Alternative nonheparin anticoagulation must be administered concurrently. In most cases, a direct thrombin inhibitor (DTI, e.g., bivalirudin, lepirudin, or argatroban) is substituted for heparin until adequate prolongation of the international normalized ratio (INR) can be achieved with warfarin. Initiation of warfarin alone is contraindicated for HIT treatment because the initial decreased synthesis of proteins C and S enhances the patient's prothrombotic state. Platelet transfusions should be held unless the patient is severely thrombocytopenic ($<20 \times 10^9$/L) with signs of bleeding. Use of DOACs (e.g., rivaroxaban, apixaban, dabigatran, edoxaban) is being investigated.[120]

Typically, PF4/heparin immune complexes are cleared from the circulation within 3 months. If possible, patients experiencing HIT should avoid future exposure to UFH; however, several reports describe subsequent limited perioperative reexposure to UFH after laboratory testing to ensure absence of PF4/heparin immune complexes. If titers remain high, treatment with plasmapheresis for rapid antibody clearance is an alternative plan, but risks and benefits should be discussed with the hematologists.[121] Otherwise, bivalirudin, the shortest acting DTI, is the alternative agent for anticoagulation while on CPB.

MONITORING COAGULATION

Traditionally, perioperative coagulation monitoring has focused on (1) preoperative testing to identify patients at increased risk for perioperative bleeding and (2) intraoperative monitoring of heparin therapy during cardiac and vascular surgery. The ideal test for perioperative coagulation should be simple to perform, accurate, reproducible, diagnostically specific, and cost effective. No current coagulation monitor meets these expectations; however, integrating results from multiple forms of monitoring may provide valuable diagnostic insight into perioperative coagulopathies.

COMMON LABORATORY-BASED MEASURES OF COAGULATION

Prothrombin Time

The PT assesses the integrity of the extrinsic and common pathways of plasma-mediated hemostasis. It measures time required in seconds for clot formation to occur after mixing a sample of patient plasma with tissue factor (thromboplastin) and calcium. It is sensitive to deficiencies in fibrinogen, and factors II, V, VII, or X. As three of these factors have vitamin K-dependent synthesis (factors II, VII, and X), the PT assay has been used to monitor anticoagulation with vitamin K antagonists (VKAs) such as warfarin. The thromboplastin reagent, derived from animal or recombinant sources, can vary in its ability to bind factor VII and initiate coagulation, which limits interlaboratory comparisons. Given the importance of monitoring PT results for patients on long-term warfarin therapy, the INR was introduced as a means of normalizing PT results among different laboratories.[122]

Thromboplastin reagents are tested against an international recombinant standard and assigned an international sensitivity index (ISI) based on the results. The INR subsequently is calculated as INR = $(\text{patient PT}/\text{standard PT})^{\text{ISI}}$, in which the standard PT represents the geometric mean of multiple normal samples from the testing laboratory. Institution of the INR substantially reduced interlaboratory variations. The PT is more sensitive at detecting decreases in factors VII and X than levels of fibrinogen and factors II and V; however, due to variations in thromboplastin reagents, factor levels as low as 40% to 50% may not prolong the PT.[123]

Any prolongation of the PT should be assessed further with mixing studies to determine whether delayed clot formation is attributable to a coagulation factor deficiency or an inhibitor (e.g., antiphospholipid antibody, fibrin degradation products). The mixing study is performed by mixing the patient's plasma sample with "normal" donor plasma. In the case of a coagulation factor deficiency, time to clot formation will correct whereas time to clot formation will not correct in the presence of an inhibitor.

Activated Partial Thromboplastin Time

The aPTT assesses integrity of the intrinsic and common pathways of plasma-mediated hemostasis. It measures the time required in seconds for clot formation to occur after mixing a sample of patient plasma with phospholipid, calcium, and an activator of the intrinsic pathway of coagulation (e.g., celite, kaolin, silica, or ellagic acid). The aPTT is more sensitive to deficiencies in factors VIII and IX than other factors in the intrinsic and common pathways. In most cases, coagulation factor levels below 30% to 40% of normal are detectable; however, aPTT reagents vary in their sensitivity to factor concentrations and may not be prolonged until levels drop below 15% for some factors.[124] Additionally, as there is no reference standard reagent for the aPTT analogous to the INR for PT, individual institutions must set their own normal ranges and aPTT values cannot be compared between laboratories.

Monitoring anticoagulation during cardiac and vascular surgery remains necessary given the widely acknowledged pharmacokinetic and pharmacodynamic response to heparin. Patient-specific factors affecting response to heparin include age, weight, intravascular volume, and concentrations of AT, heparin cofactor II, PF4, and other heparin-binding proteins. Therefore, patients experience widely divergent anticoagulant responses to identical weight-based doses of heparin. In situations where heparin therapy must be initiated in patients with a baseline aPTT prolongation (lupus anticoagulant or factor inhibitors), alternative tests such as anti-factor Xa activity or heparin level measurements must be used.

Anti-Factor Xa Activity

The anti-factor Xa activity assay or factor Xa inhibition test is being used with increasing frequency to monitor heparin anticoagulation instead of, or in addition to, the aPTT assay. The assay involves combining patient plasma with reagent factor Xa and an artificial substrate that releases a colorimetric signal after factor Xa cleavage, thereby providing a functional assessment of heparin anticoagulant effect.[125] While aPTT values can be affected by several patient factors such as coagulation factor deficiencies, factor inhibitors, or the presence of lupus anticoagulant, measurement of the heparin-bound AT inhibition of factor Xa activity is not influenced by these variables. Anti-factor Xa testing can also be used to measure the effect of other anticoagulants such as LMWH, fondaparinux, and factor Xa inhibitors. As with the aPTT assay, the anti-factor Xa test lacks adequate standardization, and activity levels vary based on the type of assay used, and patient population assayed.[126] Furthermore, significant discordance between aPTT and anti-factor Xa results can be observed in hospitalized patients receiving heparin therapy.[127] Data supporting the use of anti-factor Xa over aPTT is sparse; however, it may be helpful to use anti-factor Xa testing in combination with the aPTT to monitor both heparin effect and generalized coagulation status, respectively.

Platelet Count and Bleeding Time

The platelet count remains a standard component in screening for coagulation abnormalities. Automated platelet counts are performed in bulk using either optical-based or impedance-based measurements. Recommendations regarding optimal platelet counts prove somewhat arbitrary, but platelet counts exceeding 100,000 μL commonly are associated with normal hemostasis. Abnormally low platelet counts merit further assessment, including a visual platelet count from a blood smear. Sample hemodilution and platelet clumping are common etiologies for falsely low platelet counts.

With the growth of point-of-care platelet function monitors, the bleeding time has declined in popularity. Limitations of the bleeding time include poor reproducibility, time needed to perform the test, and potential for scarring. Furthermore, the bleeding time is affected by numerous confounding variables, including skin temperature, skin thickness, age, ethnicity, anatomic test location, and a host of other factors.[128] In general, the bleeding time is not predictive of bleeding and for that reason its use as a preoperative screening test to assess bleeding risk is not recommended.[129]

COMMON POINT-OF-CARE MEASURES OF COAGULATION

Although laboratory-based measures of coagulation remain the mainstay of preoperative coagulation testing, increasing availability of sensitive and specific point-of-care coagulation monitoring may soon offer opportunities to direct blood component and hemostatic drug therapy more specifically without delays inherent to standard laboratory testing. Commercially available point-of-care tests applicable in the perioperative setting may be considered in four broad categories: (1) functional measures of coagulation that measure the intrinsic ability of blood to generate clot, (2) heparin concentration monitors, (3) viscoelastic measures of coagulation, and (4) platelet function monitors.

Activated Clotting Time

The activated clotting time (ACT), described by Hattersley in 1966 as a variation of the Lee-White whole blood clotting time, employs a contact activation initiator, typically celite (diatomaceous earth) or kaolin, to accelerate clot formation and reduce time for assay completion.[130] Current commercial ACT monitors automate clot detection. One of the more widely available ACT monitors uses a glass test tube containing a small magnet (Hemochron Response Whole Blood Coagulation System, ITC, Edison, NJ). After adding sample blood, the tube is placed into the analyzer and the tube is rotated slowly at 37°C, allowing the magnet to maintain contact with a proximity detection switch. As fibrin clot forms, the magnet becomes entrapped and dislodged from the detection switch, thereby triggering an alarm to signal completion of the ACT. Another ACT device uses a "plumb bob" flag assembly that is raised and released repeatedly to settle in the sample vial containing blood and contact activator (Hepcon HMS Plus, Medtronic, Minneapolis, MN). With clot formation, the flag descent slows, which triggers an optical detector and sets off an alarm to signal completion of the ACT.

The ACT in normal individuals is 107 ± 13 seconds. Because the ACT measures clot formation by way of intrinsic and common pathways, heparin and other anticoagulants prolong time to clot formation. The ACT proves somewhat resistant to platelet dysfunction and thrombocytopenia. ACT testing remains a popular perioperative coagulation monitor because of its simplicity, low cost, and linear response at high heparin concentrations. Limitations of ACT monitoring include lack of sensitivity at low heparin concentrations and poor reproducibility.[131] Further limitations of the ACT include artefactual prolongation of results with hemodilution or hypothermia, and values beyond 600 seconds exceed the linear response range for the assay. Although duplicate measurements improve results, newer electrochemically based ACT analyzers (i-STAT, Abbott, Princeton, NJ) improve reproducibility such that single ACT determinations may prove adequate.

Heparin Concentration Measurement

Protamine titration remains the most popular point-of-care method for determining heparin concentration in perioperative settings. Protamine, a strongly basic polycationic protein, directly inhibits heparin in a stoichiometric manner. In other words, 1 mg of protamine will inhibit 1 mg (~100 units) of heparin, thereby forming the basis for protamine titration as a measure of heparin concentration. As increasing concentrations of protamine are added to a sample of heparin-containing blood, time to clot formation decreases until the point at which the protamine concentration exceeds heparin concentration to delay clot formation. If a series of blood samples with incremental doses of protamine are analyzed, the sample in which the protamine and heparin concentrations are most closely matched will clot first. This methodology allows for an estimate of heparin concentration. Assuming that the heparin-protamine titration curve for an individual patient remains constant throughout the operative period, protamine titration methods may estimate heparin doses required to achieve a desired plasma heparin concentration or the protamine dose needed to reverse a given heparin concentration in blood.[132] Current point-of-care heparin concentration monitoring employs automated measurement techniques (Hepcon HMS Plus, Medtronic, Minneapolis, MN). The advantages of measuring heparin concentration include sensitivity for low heparin concentrations as well as relative insensitivity to hemodilution and hypothermia. A major limitation of heparin concentration monitoring is failure to assess directly for an anticoagulant effect. For example, consider a patient with a homozygous deficiency of AT; in this case, heparin concentration determination alone would fail to identify the lack of anticoagulant effect after heparin administration.

Viscoelastic Measures of Coagulation

Initially developed in the 1940s, viscoelastic measures of coagulation have undergone a resurgence in popularity. The unique aspect of viscoelastic monitors lies in their ability to measure the entire spectrum of clot formation in whole blood from early fibrin strand generation through clot retraction and fibrinolysis. The early TEG developed by Hartert in 1948 has evolved into two independent viscoelastic monitors: the modern TEG (TEG 5000 Thromboelastograph Hemostasis Analyzer System, Haemoscope, Braintree, MA) and ROTEM (TEM Systems, Durham, NC).[133] In the case of the TEG 5000, a small (0.35-mL) sample of whole blood is placed into a disposable cuvette within the instrument. The cuvette is maintained at a temperature of 37°C and continuously rotates around an axis of approximately 5 degrees. A sensor "piston" attached by a torsion wire to an electronic recorder is lowered into the blood within the cuvette. Addition of an activator, most often kaolin or celite, initiates clot formation. As the fibrin-platelet plug evolves, the piston becomes enmeshed within the clot, transferring rotation of the cuvette to the piston, torsion wire, and electronic recorder.[134]

Although variables derived from the TEG tracing do not coincide directly with laboratory-based tests of coagulation, the TEG depicts characteristic abnormalities in clot formation and fibrinolysis. Various parameters describing clot formation and lysis are identified and measured by the TEG.

For example, the R value (reaction time) measures time to initial clot formation. The R value may be prolonged by a deficiency of one or more plasma coagulation factors or inhibitors such as heparin. Maximum amplitude provides a measure of clot strength and may be decreased by either qualitative or quantitative platelet dysfunction or decreased fibrinogen concentration. The α angle and K (BiKoatuguli-erung or coagulation) values measure rate of clot formation and may be prolonged by any variable slowing clot generation such as a plasma coagulation factor deficiency or heparin anticoagulation. Modification of clotting activators may be incorporated to assess platelet or fibrin contributions to clot strength.

In a somewhat analogous manner, ROTEM measures viscoelastic changes in a sample of whole blood subjected to coagulation activation. Specific activators differ from that of the TEG with resulting quantitative measures termed (1) coagulation time (seconds), (2) α angle (clot formation time; seconds), (3) maximal clot firmness (MCF; millimeter), and (4) lysis time (LT; second)(Fig. 50.5 on TEG in attached file).

In contrast to TEG and ROTEM, an alternative viscoelastic measure of coagulation (Sonoclot Analyzer, Sienco Inc., Arvada, CO) immerses a rapidly vibrating probe into a 0.4-mL sample of blood. As clot formation proceeds, impedance to probe movement through the blood increases to generate an electrical signal and characteristic clot signature. The analyzer signature may be used to derive the ACT and to provide information regarding clot strength and presence of fibrinolysis.

Viscoelastic monitors generate characteristic diagrams by translating mechanical resistance to sensor movement within a sample of whole blood to an electronic waveform subject to quantitative analysis.[133] One of the more common applications for viscoelastic monitoring has been real-time detection of excess fibrinolysis during liver transplantation or cardiac surgery. Evidence suggests that viscoelastic monitoring may prove beneficial in differentiating surgically related bleeding from that due to a coagulopathy. When used as one component of a diagnostic algorithm, both TEG and ROTEM have been demonstrated to reduce blood administration.[135,136] More widespread application of viscoelastic monitoring has been hindered by lack of specificity associated with abnormal findings and qualitative assay interpretation.[137] Digital automation of these instruments has simplified interpretation and improved reproducibility.

Platelet Function Monitors

Assessment of platelet function has proved challenging for several reasons. Historically, tests of platelet function are costly, time consuming, and technically demanding. Platelet dysfunction may occur as a result of diverse inherited or acquired disorders affecting surface receptors involved in adhesion or aggregation, storage granules, internal activation pathways, phospholipid membranes, or other mechanisms.[138] Lack of standardized quality controls necessitates use of local donor blood to establish normal control ranges. Complicating assessment further is the fact that platelets are highly susceptible to activation or desensitization during sample collection, transport, storage, and processing.

The technique for platelet aggregometry was developed in the 1960s and soon became the gold standard for assessment of platelet function.[139] The classic method involves centrifugation of patient blood to obtain platelet-rich plasma, which is then analyzed in a cuvette at 37°C placed between a light source and photocell. Addition of platelet agonists such as ADP, epinephrine, collagen, and ristocetin, stimulates platelet aggregation, which in turn results in a decrease in turbidity of the solution and an increase in light transmission. Patterns based upon the kinetics and amplitude of response to these various agonists are associated with specific platelet disorders and aid in diagnosis.[140] In an effort to decrease the labor required to prepare the platelet rich plasma solution as well as to include the effect of RBCs and plasma proteins on platelet function, a technique for whole blood aggregometry was developed.[141] Whole blood aggregometry uses platinum electrodes onto which platelets adhere. Platelet aggregation induced by agonists results in increased adhesion of aggregates to the electrodes, raising the impedance which is measured over time. A multichannel system (Multiplate Analyzer, Roche Diagnostics, Indianapolis, IN) is available and is used to diagnose platelet dysfunction as well as monitor anti-platelet therapy.[142] Flow cytometry employing fluorescent-labeled antibodies provides another sensitive method for quantitating platelet activation, responsiveness, and surface receptor availability.[143] Despite representing standards of care, these measurements remain technically challenging, costly, and time-consuming laboratory-based assays.

Although viscoelastic measures of coagulation (i.e., TEG or ROTEM) may detect platelet dysfunction, the sensitivity and specificity are limited. Incorporation of a platelet mapping assay into TEG provides a method for viscoelastic measurement of drug-induced platelet inhibition with reasonable correlation to optical aggregometry.[134]

Fortunately, an increasing array of platelet function assays specifically designed as point-of-care instruments are becoming available.[140] As a measure of primary hemostasis, a platelet function analyzer (PFA-100, Siemens, Tarrytown, NY) increasingly has replaced the bleeding time in assessment of hemostasis. The PFA-100 incorporates high-shear conditions to simulate small vessel injury in the presence of either ADP or epinephrine, both potent platelet activators.[144] Time to clot-mediated aperture occlusion is reported as closure time. The PFA-100 has proven effective in detecting vWD and aspirin-mediated platelet dysfunction. This instrument, as a component of a standardized screening protocol, reduces time to identify and classify platelet dysfunction. Limitations of the PFA-100 include interference by thrombocytopenia and hemodilution.

Many other different point-of-care platelet function testing devices are on the market today. It is important to keep in mind that monitors from different manufacturers measure differing aspects of platelet-mediated or plasma-mediated hemostasis. When using different instruments, results may vary from “severe” platelet dysfunction to “no platelet dysfunction” in a single sample of blood. Before adopting any point-of-care monitoring, an understanding of the quality assurance requirements, test methodology, and concomitant strengths and weaknesses are essential to inform patient care. Also, in considering any point-of-care coagulation testing, it must be recognized that results will not necessarily mirror those reported from laboratory-based

testing because of differences between using whole blood samples for testing as opposed to plasma or processed platelets. Reagent sensitivities can vary across manufacturers and lots. Hopefully, further advances in point-of-care coagulation monitoring will offer the opportunity for clinicians to make informed, bedside decisions about transfusion therapy and hemostatic drug administration to minimize perioperative bleeding and adopt effective patient blood management practices.

Antithrombotics, Thrombolytics, and Procoagulant Drugs

In the following sections, we will briefly review some common medications used to decrease or increase clot formation and then examine perioperative management strategies to reverse anticoagulants. This is not intended to be an exhaustive list of all FDA-approved drugs, so only more commonly used medications are discussed here.

Starting with antithrombotic drugs, these drugs are usually used to reduce the formation of blood clots in the setting of coronary or cerebral atherosclerosis or after vascular thrombosis. They can be further subdivided into antiplatelet agents and anticoagulants (Table 50.1).

TABLE 50.1 Common Classes of Antithrombotics, Thrombolytics, and Procoagulants

Category	Subcategory	Generic Drug Names
Antiplatelet agents	Cyclooxygenase inhibitors	Aspirin, NSAIDS
	P2Y12 receptor antagonists	Ticlopidine, clopidogrel, prasugrel, cangrelor, and ticagrelor
	Platelet GPIIb/IIIa antagonists	Abciximab, eptifibatide, and tirofiban
Anticoagulants	Vitamin K antagonists	Warfarin
	Heparin	UFH, LMWH, fondaparinux
	Direct thrombin inhibitors	Argatroban, bivalirudin (IV) Desirudin (SQ) Dabigatran (PO)
	Factor Xa inhibitors	Rivaroxaban, apixaban, edoxban
Thrombolytics	Fibrin-specific agents	Alteplase, reteplase, tenecteplase
	Non-fibrin-specific agents	Streptokinase
Antifibrinolytics	Lysine analogs	Tranexamic acid, epsilon-aminocaproic acid
Factor Replacements	Recombinant Factor VIIa	
	Factor VIII-vWF	
	Prothrombin complex concentrates	3-factor PCC; 4-factor PCC, activated PCC, FEIBA
	Fibrinogen concentrates	

FEIBA, Factor VIII Bypass Activity; *IV,* intravenous; *LMWH,* low-molecular-weight heparin; *NSAIDS,* nonsteroidal antiinflammatory drugs; *PCC,* prothrombin complex concentrate; *PO,* per os, by mouth; *SQ,* subcutaneous; *UFH,* unfractionated heparin; *vWF,* von Willebrand factor.

ANTIPLATELET AGENTS

Antiplatelet agents inhibit thrombus formation by inhibiting platelet aggregation and/or adhesion to clot or damaged endothelium. Depending on the drug, they can work either reversibly or irreversibly. Most common antiplatelet agents can be divided into: (1) cyclooxygenase (COX) inhibitors, (2) P2Y12 receptor antagonists, and (3) platelet GPIIb/IIIa antagonists, although there are several other classes available such as phosphodiesterase inhibitors, protease-activated receptor-1 antagonists, adenosine reuptake inhibitors, and thromboxane inhibitors.

Cyclooxygenase Inhibitors

Aspirin and NSAIDS are the two primary members of this class. There are two forms of the cyclooxygenase enzyme: COX-1 and COX-2. COX-1 maintains the integrity of the gastric lining and renal blood flow and initiates the formation of thromboxane A_2 (TxA_2), which is important for platelet aggregation. COX-2 is responsible for synthesizing the prostaglandin mediators in pain and inflammation.

Aspirin

Aspirin is a non-selective and irreversible COX inhibitor. It acetylates a serine residue on COX-1 and prevents the production of TxA_2 in platelets.[145] COX-2, which leads to antiinflammatory and analgesic effects, is 170 times less sensitive than COX-1 to aspirin so only at high doses can aspirin irreversibly inhibit both COX-1 and COX-2.[146] Because platelets are anuclear, they are unable to synthesize new COX-1 once aspirin has irreversibly inhibited the enzyme. Consequently, despite its short half-life of approximately 15 to 20 minutes, aspirin's inhibitory effect persists through the platelet lifespan of 7 to 10 days.[147]

The recovery of platelet function after aspirin depends on platelet turnover. Generally, megakaryocytes generate 10% to 12% of platelets daily, so near normal hemostasis is expected in 2 to 3 days after the last dose of aspirin with typical platelet turnover. High platelet turnover diseases, which result from increased production (e.g., essential thrombocythemia) or increased consumption (e.g., inflammation), may require more frequent than once daily aspirin dosing.[148] Immediate reversal of aspirin for emergencies can be achieved with platelet transfusions.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Most NSAIDS are nonselective, reversible COX inhibitors and therefore provide antipyretic, analgesic, and antiplatelet aggregation effects.[149] Platelet function normalizes 3 days after discontinuing the use of NSAIDS. Selective COX-2 antagonists such as celecoxib were introduced in the late 1990s to provide antiinflammatory, analgesic, and antipyretic activity without the gastrointestinal complications,[150] but clinical trials with selective COX-2 antagonists have reported increased risks for cardiovascular complications.[151] COX-2 specific inhibitors do not affect platelet function because platelets do not express COX-2. The increased cardiovascular risk is thought to be due to inhibition of PGI_2 without inhibition of TxA_2, thus tipping the balance toward thrombosis. Current recommendations are to use COX-2 inhibitors only when necessary for pain and then with the lowest effective dose possible after weighing the risks and benefits.[152]

P2Y12 RECEPTOR ANTAGONISTS

These drugs (ticlopidine, clopidogrel, prasugrel, cangrelor, and ticagrelor) interfere with platelet function by inhibiting the P2Y12 receptor, which inhibits platelet adhesion and aggregation by preventing the expression of GPIIb/IIIa on the surface of activated platelets.[153] Ticlopidine, clopidogrel, and prasugrel are members of a class known as thienopyridines, and are pro-drugs requiring hepatic metabolism to generate the active metabolite that then irreversibly inactivates the ADP-binding site of the P2Y12 receptor.[154] Ticagrelor and cangrelor are reversible inhibitors.

Clopidogrel (Plavix) is the most commonly prescribed agent in this class. Platelet functions normalize 7 days after discontinuing clopidogrel and 14 to 21 days after discontinuing ticlopidine. Because clopidogrel is a pro-drug and requires CYP2C19 for activation, it has wide interindividual variability in inhibiting ADP-induced platelet function. Although many factors may be involved in this variability, genetic polymorphism of CYP2C19 along with ABCB1, which affects the intestinal permeability and oral bioavailability of clopidogrel, are thought to play a significant role.[155] Patients treated with clopidogrel who have decreased CYP2C19 and ABCB1 activity were shown to have increased risk of major cardiovascular events.[156] The FDA put a black box warning on clopidogrel to make patients and healthcare providers aware that CYP2C19-poor metabolizers, representing up to 14% of patients, are at high risk of treatment failure and that genotype testing may be helpful prior to drug initiation.[157]

Ticagrelor binds to the P2Y12 receptor at a different site than the thienopyridines, and causes a conformational change of the receptor.[158] While ticagrelor needs to undergo metabolism to an active metabolite, both the parent drug and the active metabolite have anti-platelet effects.[159] Genetic polymorphisms do not appear to be clinically relevant for this drug.[160] Because it is much shorter acting than clopidogrel, ticagrelor must be dosed twice daily, which may be of benefit prior to surgery.

The newest drug in this group is cangrelor. It is the only one available for intravenous administration, and like ticagrelor, it changes the conformation of the P2Y12 receptor, resulting in inhibition of ADP-induced platelet aggregation.[158] It received FDA approval in 2015 for adult patients undergoing percutaneous coronary intervention (PCI). This drug has the fastest onset of action (seconds), and platelet function normalizes within 60 minutes after drug discontinuation.[161] This rapid onset may allow for bridging therapy in patients with drug-eluting stents who require surgery.

GLYCOPROTEIN IIB/IIIA INHIBITORS

Glycoprotein IIb/IIIa inhibitors (GPI) (abciximab, eptifibatide, and tirofiban) work to prevent platelet aggregation by decreasing the binding of fibrinogen and vWF to glycoprotein IIb/IIIa receptors on the surface of activated platelets.[162] They are given intravenously in order to: (1) stop ongoing arterial thrombosis or (2) eliminate excessive platelet reactivity in diseased vessels so that occlusive thrombi and restenosis do not occur. Their use was highly touted in the past with balloon angioplasty where acute closure was a feared complication. Now with the introduction of stents and P2Y12 receptor antagonists, GPI have become less popular in routine PCI because of the associated bleeding risk and their use is only recommended in a subset of patients with high risk angiographic features or those not loaded adequately with dual antiplatelet agents.[163] Although abciximab has a short plasma half-life (approximately 10 minutes), its effects on platelet function can be seen for much longer, even after the infusion has been stopped. One rare, but serious side effect to be aware of, abciximab can produce thrombocytopenia immediately after drug administration in a small proportion of patients. Mild thrombocytopenia (platelet count $<100 \times 10^9$/L) developed more frequently in patients treated with the drug than control subjects (4.2% vs. 2.0%; $P < .001$).[164]

ANTICOAGULANTS

Vitamin K Antagonists

Warfarin, the most frequently used oral VKA in the United States, inhibits the vitamin K-dependent carboxylation of coagulation factors II, VII, IX, and X and proteins C and S. Warfarin is highly effective in reducing the risk of venous and arterial thromboemboli, and is still the anticoagulant of choice for patients with valvular atrial fibrillation and mechanical heart valves despite the popularity and increased utilization of DOACs for nonvalvular atrial fibrillation. [165]

Warfarin has a long half-life (40 hours) and the complete anticoagulant effect can take 3 to 4 days to emerge because of the long half-lives of the preexisting coagulation factors. Prothrombin (factor II) has the longest half-life (~60 hours). Factor VII and protein C have the shortest half-lives (3-6 hours).[166] Because of this long initiation period, patients at high risk for thromboembolism must be bridged with another anticoagulant (usually UFH or LMWH) until the target INR is achieved. Also, early reductions in the anticoagulant protein C can cause an imbalance toward a hypercoagulable state if warfarin is started alone, resulting in thrombosis or warfarin-induced skin necrosis.

Warfarin is monitored using the INR, and the therapeutic range for warfarin anticoagulation is generally an INR of 2.0 to 3.0, except for patients with mechanical heart valves, where higher values are necessary (INR 2.5-3.5). The INR is not calibrated to evaluate non-warfarin deficiencies such as liver disease and should not be used to evaluate therapeutic effects of other anticoagulants. Warfarin has a very narrow therapeutic window and can be easily affected by drug-drug interactions and patient variability. The need for frequent laboratory monitoring makes warfarin a difficult drug for patients to maintain compliance and the reported time in therapeutic range is only about 65% ± 20% in patients with atrial fibrillation.[167]

Warfarin's pharmacology can be affected by genetic variations in the metabolism of the drug (CYP2C9) and in the production of a vitamin K epoxide reductase enzyme (VKORC1), which reduces vitamin K after it has been oxidized. Recent meta-analyses of randomized trials found that pharmacogenetics testing for polymorphisms unfortunately did not reduce rates of bleeding or thromboembolism.[168] Current recommendations are to only perform pharmacogenetics testing in patients who consistently have INRs outside the therapeutic range or who have an adverse event while on therapy.[169]

Unfractionated Heparin

UFH can be isolated from porcine or bovine intestines and is a mixture of different length polysaccharides with a high molecular weight (mean molecular weight around 15,000 daltons or 35-45 polysaccharide units).[170] UFH binds to AT and indirectly inhibits thrombin (factor IIa) and factor Xa. Benefits of heparin are its short half-life and full reversibility with protamine. Heparin does not have any fibrinolytic activity, so it will not lyse an existing clot.

Full-dose heparin for cardiac surgery is administered as an intravenous bolus of 300 to 400 U/kg. An ACT greater than 400 to 480 seconds is usually considered safe for initiation of CPB. Patients may be resistant to UFH if they have a hereditary deficiency of AT or an acquired deficiency of AT from prolonged heparin administration. The incidence of heparin resistance during CPB is reported at approximately 21%.[171] Simply increasing the dose of heparin in patients with an AT deficiency is often not effective. For these patients, treatment should be with fresh frozen plasma (FFP) transfusions or AT concentrate, which will replenish AT levels and restore heparin response.[172] Other causes of heparin resistance can be due to increased heparin clearance, increased levels of heparin-binding proteins, or elevations of fibrinogen and factor VIII levels.

Low Molecular Weight Heparin and Fondaparinux

LMWH, produced by cleaving UFH into shorter fragments (mean molecular weight approximately 4000 daltons, approximately 15 saccharide units)[173] and fondaparinux, a synthetic pentasaccharide (mean molecular weight 1700 daltons) of the AT binding region of heparin, act more specifically via AT to inhibit factor Xa. LMWH and fondaparinux do not affect the aPTT assay, and coagulation testing is usually not needed. Anti-factor Xa activity levels may be necessary in patients who may have unpredictable drug levels (e.g., renal failure, pregnancy, and body weight less than 50 kg or more than 80 kg).

LMWH has a longer half-life than heparin and can be administered subcutaneously either once or twice daily. LMWH is primarily excreted by the kidney, so its half-life is prolonged in patients with renal failure. Approximately 25% to 50% of LMWH molecules contain 18 or more saccharide units and can inhibit factor Xa and thrombin, while the remaining 50% to 75% of LMWH molecules contain <18 saccharide units and only inhibit factor Xa. [174] Protamine requires more than 14 saccharide units in the heparin molecule for interaction. [175] Therefore, protamine is only partially effective in reversing LMWH. It does not completely abolish the anti-Xa activity, but it may neutralize the higher molecular weight fractions of LMWH.

Fondaparinux has a much longer half-life (17-21 hours) and can be dosed daily.

Because it is only 5 saccharide units, protamine is not effective for reversing fondaparinux.[176] Because antigen formation by the PF4/heparin complex requires a polysaccharide chain of at least 8 to 10 saccharides, fondaparinux-associated HIT is unlikely to occur,[177] and only eight cases of possible fondaparinux-associated HIT have been reported in the literature.[178] Currently, fondaparinux is not FDA approved for use in HIT, but there is considerable positive anecdotal experience in the literature (e.g., decreased bleeding risk) when compared with DTIs.[179]

Direct Thrombin Inhibitors

DTIs bind directly to thrombin and do not require a cofactor such as antithrombin to exert their effect. All DTIs inhibit thrombin in its free (soluble) and fibrin-bound (insoluble) states, unlike heparin, which only has effect on free thrombin. Other advantages over heparin include: lack of binding to other plasma proteins that leads to a more predictable anticoagulant effect, and no concern for developing an immune-mediated thrombocytopenia.

Hirudin is a naturally occurring anticoagulant found in leeches, while argatroban and bivalirudin are synthetic agents. Argatroban, with a half-life of 45 minutes, is the preferred DTI in patients with renal insufficiency because it is eliminated by the liver. It reversibly binds to the active site on thrombin. Argatroban is FDA approved for the prophylaxis and treatment of thrombosis and for PCI anticoagulation in patients with HIT. Clinical effects are usually monitored with aPTT or ACT in the operating room. Dosing goals are to maintain an aPTT 1.5 to 3 times baseline. Because argatroban prolongs thrombin-dependent coagulation, the PT and INR will be prolonged as well, which can complicate transition to warfarin therapy for long-term anticoagulation.[180]

Bivalirudin, a 20-amino acid synthetic analogue of hirudin, is a reversible DTI, and is metabolized by proteolytic cleavage and hepatic metabolism.[181] It has the shortest half-life among the intravenous DTIs and is the drug of choice for patients with both renal and hepatic dysfunction, although dose adjustments are still necessary. In studies, bivalirudin has been shown to have better efficacy in preventing primary outcomes with lower bleeding rates when compared with UFH for percutaneous transluminal coronary angioplasty for unstable or postinfarction angina,[182] and for use as an alternative to heparin in patients with HIT undergoing PCI.[183]

Desirudin was approved in 2010 and is the only DTI available for subcutaneous administration. An early, small, open label study (16 patients) showed that desirudin may be a potentially cost-effective alternative to argatroban for patients with suspected HIT.[184] Desirudin also has more predictable pharmacokinetics, and dosage adjustments and aPTT monitoring may be unnecessary in patients with a creatinine clearance greater than 30 mL/min.[185]

Direct Oral Anticoagulants

Several new oral anticoagulants have been introduced into the market over the past 10 years. These new drugs have more predictable pharmacokinetics and pharmacodynamics and fewer drug-drug interactions, allowing them to be dosed without daily laboratory monitoring. The drawback has been the lack of specific antidotes for anticoagulation reversal, but this is slowly changing with the introduction of idarucizumab.

Most DOACs are approved for prevention of venous thromboembolism after hip or knee replacement surgery, treatment and secondary prevention of venous thromboembolism, and prevention of stroke in nonvalvular atrial fibrillation. Many are also being studied for use in secondary prevention of coronary events after acute coronary syndrome, prevention of thrombosis in elective PCI, and prevention of thrombus formation on mechanical heart valves. The results from early preclinical trials have been positive and encourage further randomized trials, so increased impact of these agents in the future is expected.[186] The DOACs have a shorter half-life than warfarin and have demonstrated noninferior efficacy to warfarin. A meta-analysis of phase II and phase III randomized clinical trials comparing DOACs with VKAs in patients with atrial fibrillation showed that use of DOACs was associated with a significant reduction in major bleeding (Relative risk [RR] 0.86, 95% CI 0.72-1.02) and a significantly decreased risk of intracranial hemorrhage (RR 0.46, 95% CI 0.39-0.56).[187]

Dabigatran (Pradaxa), an oral DTI, was the first new antithrombotic agent approved for the prevention of ischemic stroke in patients with non-valvular atrial fibrillation since warfarin. When given at a dose of 150 mg twice daily, dabigatran was shown to reduce the risk of stroke while having a similar bleeding risk as warfarin at an INR of 2.0 to 3.0.[188] Although the bleeding risk is similar, the bleeding profile does differ between the two drugs. Dabigatran increases the risk of major gastrointestinal bleeding but lowers the risk of intracranial bleeding when compared with warfarin.[189] Dabigatran is predominantly eliminated by the kidneys, so the dose should be reduced in patients with a creatinine clearance less than 30 mL/min.

Monitoring of dabigatran therapy is difficult because the perfect laboratory test does not exist. The aPTT does not become linear until dabigatran concentrations are quite high (>200 ng/mL).[190] The TT is very sensitive to dabigatran, so while it is useful to detect any presence of the drug, it cannot be used to quantify the amount of drug present.[191] If available, dilute TT or ecarin clotting time are both linear at clinically relevant dabigatran concentrations and are the tests of choice if monitoring is necessary.[192]

Direct Xa inhibitors, rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa) are agents whose activity is directed against the active site of factor Xa. Factor Xa inhibitors have been associated with fewer strokes and embolic events, fewer intracranial hemorrhages, and lower all-cause mortality compared with warfarin.[193] A comparison of apixaban versus warfarin in patients with atrial fibrillation showed a reduction in stroke risk along with a significant reduction in major bleeding.[194] The anti-factor Xa assays are the tests best suited for monitoring the effects of the direct Xa inhibitors, but assays must be individually calibrated for each drug.[192]

THROMBOLYTICS

Thrombolytic therapy is used to break up or dissolve blood clots. These medications are most commonly used during acute myocardial infarctions, strokes, massive pulmonary embolus, arterial thromboembolism, and venous thrombosis. Thrombolytics may be given through an intravenous line systemically or directly to the site of the blockage. Most thrombolytic agents are serine proteases that work by converting plasminogen to plasmin. Plasmin then lyses the clot by breaking down fibrinogen and fibrin. Fibrinolytic agents are divided into two categories: (1) fibrin-specific agents and (2) non–fibrin-specific agents. Fibrin-specific agents are alteplase (tPA), reteplase, and tenecteplase. They theoretically produce less plasminogen conversion in the absence of fibrin and result in less fibrinogen depletion. Non–fibrin-specific agents (e.g., streptokinase) catalyze systemic fibrinolysis. Streptokinase, produced by beta-hemolytic streptococci, is highly antigenic and can cause immunologic sensitization and allergic reactions, particularly with repeat administration even several years after previous exposure.[195] Streptokinase is not widely used in the United States but is still used internationally because of its lower cost.

t-PAs are both thrombolytics and anticoagulants because as mentioned earlier, fibrinolysis generates increased amounts of circulating fibrin degradation products, which inhibit platelet aggregation. Surgery or puncture of noncompressible vessels is contraindicated within a 10-day period after the use of thrombolytic drugs.

Time is usually of the essence when administering these drugs. Medical providers should quickly obtain a history and physical exam, review absolute and relative contraindications, (Table 50.2), order relevant laboratory tests, request necessary consultations, and proceed with decision making. Many studies have investigated the use of thrombolytics in acute pulmonary embolus, ST-elevation myocardial infarction (STEMI), and ischemic stroke. Thrombolytics are indicated in the setting of hemodynamic instability due to acute pulmonary embolus.[196] A meta-analysis in patients with massive pulmonary embolism found that systemic thrombolytic therapy decreased the composite endpoint of death and recurrent thromboembolism (9.4% vs. 19%, odds ratio 0.45, 95% CI 0.22-0.92).[197] Primary PCI is the preferred treatment for patients with acute STEMI if it can be performed by an experienced operator within 2 hours from presentation to the emergency department, but fibrinolytic therapy remains an important modality in hospitals with limited primary PCI

TABLE 50.2 Absolute and Relative Contraindications for Thrombolytics

Absolute Contraindications	Relative Contraindications
Vascular lesions	Ischemic stroke >3 months prior
Severe, uncontrolled hypertension (SBP > 185 or DBP > 110)	Active peptic ulcer
Recent cranial surgery or trauma	Current use of anticoagulant drugs
Brain tumor	Pregnancy
Ischemic stroke <3 months prior	Prolonged/traumatic CPR <3 weeks prior
Active bleeding	Major surgery <3 weeks prior

CPR, Cardiopulmonary resuscitation; *DBP*, diastolic blood pressure; *SBP*, systolic blood pressure.

availability. Early thrombolysis was associated with a lower mortality rate. When compared between less than 2 hours versus greater than 4 hours from time of symptom presentation to thrombolysis administration, 30-day mortality was decreased with earlier administration (5.5% vs. 9%).[198] For stroke care, the primary goal is to restore blood flow to ischemic regions in order to reduce stroke-related disability and mortality. Alteplase is the recommended therapy for treatment of acute ischemic stroke if treatment can be initiated within 4.5 hours of symptom onset.[199] Mechanical thrombectomy should still be considered even if thrombolysis has been administered for ischemic stroke.

PROCOAGULANT DRUGS

Anesthesiologists may use procoagulant drugs for individuals at risk of bleeding to help control blood loss during surgery. These drugs can be divided into two different classes: antifibrinolytics and factor replacements. (see Table 50.1).

Antifibrinolytics

There are two types of antifibrinolytics, the lysine analogs, epsilon-aminocaproic acid (EACA) and TXA, and a SERPIN, aprotinin. Aprotinin was removed from the US market due to concerns of renal and cardiovascular toxicity and is now only available in Europe and Canada. The lysine analogs act by competitively inhibiting the binding site on plasminogen, leading to inhibition of plasminogen activation as well as preventing plasminogen binding of fibrin, therefore impairing fibrinolysis.[200] TXA has been more thoroughly studied than EACA, but aside from subtle differences, both agents appear to have similar efficacy and have been shown to decrease perioperative blood loss.

TXA has been studied in the large CRASH-2 trial of patients admitted after trauma and was associated with a reduction in all-cause mortality (14.5% vs. 16%, P = .0035), including the risk of death due to bleeding (4.9% vs. 5.8%, P = .0077), without an increase in vascular occlusive events.[100] Subgroup analysis of the CRASH-2 data showed that early treatment (≤1 hour) after traumatic injury significantly reduced the risk of death due to bleeding events in the TXA group (RR 0.68; 95% CI, 0.57-0.82; $P < .0001$). RR was also lower 0.79 (95% CI, 0.64-0.97; P = .03) if TXA was administered between 1 and 3 hours; however, treatment after 3 hours seemed to increase death due to bleeding, with a RR of 1.44 (95% CI, 1.12-1.84; P = .004).[101]

Aside from trauma, there are also trials studying use of TXA in cardiac surgery, orthopedic surgery, neurosurgery, hepatic surgery, and obstetric and gynecology surgery. The World Maternal Antifibrinolytic Trial (WOMAN) found that administration of TXA reduced death due to bleeding in women with postpartum hemorrhage, especially if given within 3 hours of birth, and was not associated with an increase in adverse effects.[201] In a recent meta-analysis in surgical patients, TXA reduced the probability of receiving a blood transfusion by a third (risk ratio 0.62; 95% CI, 0.58-0.65; $P < .001$). [202] Fewer deaths occurred in the TXA group (risk ratio 0.61; 95% CI, 0.38-0.98; P = .04), but the effect of TXA on myocardial infarction (risk ratio 0.68; 95% CI, 0.43-1.09; P = .11), stroke (risk ratio 1.14; 95% CI, 0.65-2.00; P = .65), deep vein thrombosis (risk ratio 0.86; 95% CI, 0.53-1.39; P = .54), and pulmonary embolism (risk ratio 0.61; 95% CI, 0.25-1.47; P = .27) was inconclusive. A Cochrane review also found that TXA significantly reduced blood transfusions by 39%; however, TXA was not associated with decreased mortality in all surgeries in their analysis.[203]

Overall, the lysine analogs (TXA and EACA) appear to be inexpensive and low risk adjunctive agents that should be considered for use in major surgery or critical bleeding. The rate of thrombosis does not appear to be elevated, but further studies are necessary before this can be definitively concluded. In terms of side effects, there is a reported dose-response relationship of high-dose TXA and seizures in patients undergoing cardiac surgery.[204] The reported mechanism is TXA binding to $GABA_A$ receptors, subsequently blocking $GABA_A$-mediated inhibition in the central nervous system.[205]

Factor Replacements

Recombinant Factor VIIa. Recombinant factor VIIa (rFVIIa) increases the generation of thrombin via the intrinsic and extrinsic pathways to enhance hemostasis. The drug was originally FDA approved for use in hemophilia patients. It binds to tissue factor at the site of vessel injury and to the surface of the activated platelet, leading to activation of factor X. Both mechanisms result in a "burst" of thrombin and fibrin generation, which leads to clot formation. The half-life of rFVIIa is only 2 to 2.5 hours, so the initial dose may require repeating until the bleeding is controlled.

Successful use of rFVIIa in hemophilia patients with inhibitors generated a great deal of interest in the drug's ability to enhance hemostasis in hemorrhaging patients without a preexistent coagulation disorder. This off-label use of rFVIIa had been quite varied, and included patients with intracranial hemorrhage,[206,207] trauma,[208,209] and traumatic brain injury,[210] and patients undergoing cardiac surgery[211] and liver transplantation.[212,213] While treatment with rFVIIa reduced the progression of the hematoma following intracranial hemorrhage and reduced the risk of acute respiratory distress syndrome (risk reduction, −0.05; 95% CI, −0.02 to −0.08) in trauma patients, mortality or functional outcomes were not improved in any patient subset.[211]

As the off-label use of rFVIIa increased, there were more troubling reports of arterial and venous thromboses. A review studying the safety of off-label rFVIIa reported a higher rate of arterial thromboembolic events with the use of rFVIIa compared with placebo (5.5% vs. 3.2%, P = .003), and an increased observed rate for coronary events (2.9% vs. 1.1%, P = .002). [214] This rate was noted to be increased with age (for patients aged 65-74 years, OR 2.12; 95% CI: 0.95-4.71 and for those ≥75 years, OR 3.02, 95% CI: 1.22-7.48), as well as higher doses. Considering that no randomized controlled trial has been able to demonstrate a significant benefit in terms of intensive care stay, hospital stay, or mortality, guidelines currently recommend that rFVIIa no longer be used for the off-label indications of prevention and treatment of bleeding in patients without hemophilia.[215] Each clinician will have to weigh the risk of thromboembolic events against the benefit for the refractory bleeding patient where the "last ditch" use of rFVIIa in massive hemorrhage has not been formally assessed.

Prothrombin Complex Concentrate. PCCs are commercially available purified concentrates containing varying amounts of vitamin K-dependent coagulation factors. Three-factor PCCs differ from 4-factor PCCs in that they do not contain significant amounts of factor VII. Most of the factors are preserved in the inactive state, with the aim of decreasing thrombogenic risk; however, FEIBA is a 4-factor PCC that contains activated factor VII. The products may also contain coagulation inhibitors such as heparin, AT, protein C, and protein S to mitigate the thrombotic risk by providing more balanced replacement of procoagulant factors and anticoagulant proteins.

While PCCs are derived from human plasma, they are treated with at least one viral reduction process, reducing the risk of transfusion-transmitted infection and the lower administration volume decreases the risk of transfusion-associated circulatory overload (TACO).[216] While PCCs appear to be safe and have low risk of thrombosis, there is accumulating evidence that the level of factor II and its balance with the coagulation inhibitors may be the important key.[217]

Fibrinogen Concentrate. Fibrinogen concentrate is produced from pooled human plasma, but viral inactivation steps are incorporated into the manufacturing. It can be used to correct hypofibrinogenemia with the goals of reducing coagulopathy, bleeding, and transfusion requirements. Fibrinogen concentrate offers benefits over FFP and cryoprecipitate in terms of standardized fibrinogen content, low infusion volume, and faster time to administration due to rapid reconstitution. Alternatively, cryoprecipitate and FFP are cheaper, and they also provide additional procoagulant factors that could be beneficial during massive bleeding. In a recent meta-analysis, seven randomized controlled trials showed a significant reduction in bleeding and transfusion requirements with the use of fibrinogen concentrates, but data on mortality were lacking and there was significant heterogeneity among the trials.[218] While the data are inconclusive, some hospitals have incorporated fibrinogen concentrate into algorithms based on viscoelastic coagulation tests with the goal of reducing transfusion requirements.

Perioperative Management of Anticoagulation

The perioperative management of patients who require chronic anticoagulation or antiplatelet therapy involves balancing the risk of surgical bleeding against the risk of developing postoperative thromboembolism. Patients should be evaluated with enough time prior to elective surgery to perform these necessary risk assessments and make management decisions regarding discontinuation and reinstitution of anticoagulation or antiplatelet therapy.

VITAMIN K ANTAGONISTS

For patients taking VKAs, the current recommendation is to stop VKAs 5 days prior to surgery for those who are at low risk for perioperative thromboembolism (Table 50.3). VKAs should be restarted 12 to 24 hours postoperatively if there is adequate hemostasis. For patients at high risk of thromboembolism, bridging anticoagulation with UFH or LMWH after discontinuation of VKAs should occur. The difficulty arises in defining a plan for patients who are at moderate risk. No definitive evidence exists, so the approach chosen should be based on individual patient and surgical risk factors.[219]

TABLE 50.3 Perioperative Thromboembolism Risk Stratification

Risk	Indication
High	Mechanical heart valve
	Rheumatic valvular heart disease
	CHADS score ≥ 5
	VTE within 3 months or h/o VTE when VKAs are discontinued
Moderate	CHADS score of 3 or 4
	VTE between 3 and 12 months or h/o recurrence
	Active cancer
Low	CHADS score 0-2
	VTE > 12 months prior and no other risk factors

CHADS, Congestive heart failure, hypertension, age ≥ 75, diabetes mellitus, prior stroke; *VKA,* vitamin K antagonists; *VTE,* venous thromboembolism.

HEPARINS

For those patients receiving bridging therapy with UFH, the infusion should be stopped 4 to 6 hours prior to surgery[220] and resumed without a bolus dose no sooner than 12 hours postoperatively. In surgeries with high postoperative bleeding risk, resumption of UFH should be delayed 48 to 72 hours until adequate hemostasis has been achieved. In patients receiving bridging therapy with LMWH, the last dose of LMWH should be administered 24 hours prior to surgery and dosing should be resumed 24 hours postoperatively in low bleeding risk surgery and delayed until 48 to 72 hours postoperatively for surgeries with high bleeding risk.[219]

ASPIRIN

For patients receiving aspirin therapy, risk assessment is based on (1) the patient's risk of a perioperative cardiovascular event; (2) whether the surgery is a minor procedure, major procedure, or cardiac procedure; and (3) the timing and type of stent placement for those patients who have undergone recent PCI. Low-dose aspirin (acetylsalicylic acid, ASA) has been shown to reduce the risk of stroke and myocardial infarction by 25% to 30%,[221,222] and studies report significant increased risk with the withdrawal of low-dose aspirin because of a platelet rebound phenomenon that leads to increased thrombus stability, improved fibrin crosslinking, and decreased fibrinolysis.[223] The decision to discontinue low-dose aspirin must weigh the risks of bleeding versus the benefits of cardiovascular risk reduction. Studies suggest that perioperative aspirin use may lead to a small increase in the risk for major bleeding (2.9% vs. 2.4%, $P = .04$), [222,224] but continuation of perioperative aspirin may confer a significant reduction in myocardial infarction and other major cardiovascular events (1.8% vs. 9.0%, $P = .02$). [225]

Recommendations currently are to continue aspirin for patients who are at moderate to high risk for cardiovascular events requiring noncardiac surgery and only stop aspirin use 7 to 10 days prior to surgery for patients at low risk for cardiovascular events.[226] Patients who are having minor procedures (e.g., minor dental, dermatologic procedures, or cataract surgery) and are on aspirin for the secondary prevention of cardiovascular disease should continue taking it in the perioperative period.

Patients with coronary stents presenting for surgery are problematic because of the concerns for in-stent thrombosis that can occur with stopping antiplatelet therapy. Surgery should be delayed if possible for at least 6 weeks after bare-metal stent placement and for at least 6 months after drug-eluting stent placement.[227] If surgery is required before this time has passed, dual anti-platelet therapy should be continued unless the risk of bleeding is thought to outweigh the risk of stent thrombosis.

Many studies have examined management of aspirin therapy perioperatively; however, there is much less data for management of clopidogrel in the perioperative setting. In most clinical situations, aspirin provides benefit that outweighs the bleeding risk and should be continued unless the patient is undergoing intracranial procedures, transurethral prostatectomy, intraocular procedures, or surgeries with extremely high bleeding risk.[228] The data are inconclusive about use of bridging therapy for patients with coronary stents who require noncardiac surgery. For patients with a very high risk of stent thrombosis, bridging therapy with intravenous, reversible glycoprotein inhibitors or a reversible intravenous P2Y12 inhibitor have been suggested, but concomitant parenteral anticoagulation therapy is not recommended.

NEURAXIAL ANESTHESIA AND ANTICOAGULATION

In addition to surgical bleeding risk assessment, many patients who are on anticoagulant or antiplatelet therapy can potentially benefit from neuraxial anesthetics. Management of perioperative anticoagulation is becoming increasingly more complex with the advent of the DOACs and the number of patients who are now receiving chronic anticoagulation. There is a lack of randomized controlled trials showing safety in the timing of surgical procedures and regional anesthesia because a broad clinical experience with these drugs along with neuraxial techniques does not exist. Most guidelines in the literature are based exclusively on the pharmacokinetics and pharmacodynamics of these drugs.[229] These guidelines and recommendations will continue to be updated as evidence emerges on the bleeding risk and pharmacologic profiles of the newer anticoagulants. In the absence of concrete data, many hospital committees are setting local practice guidelines (Table 50.4). Early preoperative assessment of patients receiving anticoagulation and a multidisciplinary team approach between the patient, primary care physician, surgeon, anesthesiologist, and hematologist is essential to ensure the perioperative safety of these patients. Continued research on thromboembolic events and bleeding risk in the setting of these novel therapies is needed before official recommendations can be made regarding management.

TABLE 50.4 UCSF Guidelines for the Use of Antithrombotic Agents in the Setting of Neuraxial Procedures

Anticoagulant	Minimum Time Between the Last Dose and When Neuraxial Catheter can Occur	Minimum Time After Catheter Placement to Drug Start	Minimum Time Between Last Dose of Drug and Catheter Removal	Minimum Time Between Neuraxial Catheter Removal and When Next Dose can be Given
NSAIDs/ASA	No restrictions for catheter placement or removal			
Heparin SQ BID	No restrictions for catheter placement or removal			
Heparin SQ TID	4 h	2 h	4 h	2 h
Lovenox qD	12 h	6 h	12 h	4 h
Warfarin	5 days and INR < 1.5	Contraindicated while catheter in place		2 h
Clopidogrel	7 days	Contraindicated while catheter in place		2 h
Ticlodipine	14 days	Contraindicated while catheter in place		2 h
Dabigatran	5 days	Contraindicated while catheter in place		6 h
Rivaroxaban	3 days	Contraindicated while catheter in place		6 h
Apixaban	3 days	Contraindicated while catheter in place		6 h
Abciximab	48 h	Contraindicated while catheter in place		2 h
Eptifibatide	8 h	Contraindicated while catheter in place		2 h
Alteplase*	10 days	Contraindicated while catheter in place		10 days

*Full dose for stroke or myocardial infarction. No time restrictions for catheter placement or removal with low dose (2 mg) for catheter clearance

ASA, acetylsalicylic acid; *BID*, two times a day; *INR*, international normalized ratio; *NSAIDs*, nonsteroidal antiinflammatory drugs; *qD*, once a day; SQ, subcutaneous; *TID*, three times a day. Adapted from UCSF Guidelines for the use of antithrombotic agents in the setting of neuraxial procedures and Horlocker TT, Wedel DJ, Rowlingson JC, et al. Emergent Reversal of Anticoagulants

VITAMIN K ANTAGONISTS

The incidence of VKA-associated major bleeding is between 1.1% and 8.1% per year depending on the study design.[230,231] Some of these patients will require warfarin reversal for bleeding and other patients will require warfarin reversal prior to emergency surgery. Four-factor PCCs as opposed to three-factor PCCs are now the drug of choice for emergent reversal of oral VKA in place of FFP or rFVIIa,[232] but PCCs only provide a transient correction due to the short half-life of these factors relative to the long half-life of warfarin. Concomitant administration of vitamin K is required to restore carboxylation of the vitamin K dependent factors (VKDFs) by the liver and provide a more sustained correction after the factors in the PCC infusion have been metabolized. Intravenous administration of vitamin K gives a more rapid response than subcutaneous or oral administration.[233] The dose required depends on the clinical situation and the need to be able to re-establish anticoagulation after surgery. For instance, lower doses (3 mg) may allow for warfarin reversal during the acute event, while avoiding warfarin resistance if rapid re-establishment of a therapeutic INR is required.[234]

Rapid reversal of VKA with FFP is difficult and often unrealistic. Time to thaw ABO-compatible units is a concern, but the large volume required to raise the VKDF by 50% is often untenable, especially in a patient population prone to pulmonary, renal, and cardiac disease.[235] There are also concerns for transmission of viral diseases, and transfusion-related complications such as volume overload, TACO, and lung injury (transfusion-related acute lung injury). In a recent randomized controlled trial using 4-factor PCC to reverse VKA prior to surgery or invasive interventions, effective hemostasis was higher (90% PCC vs. 75% FFP), fluid overload was lower (3% PCC vs. 13% FFP), and thromboembolic events were similar compared with patients who received FFP (7% PCC vs. 8% FFP).[236]

DIRECT THROMBIN INHIBITORS

There are no direct reversal agents for intravenous DTIs; however, their half-lives are relatively short, so time and supportive medical care are often sufficient to manage their anticoagulant effect in acute clinical situations. For the DOACs, idarucizumab, a specific antidote for dabigatran, is a humanized antibody fragment that binds to dabigatran with an affinity 350 times greater than thrombin. The drug received FDA approval in 2015 and can completely reverse the anticoagulant effect of dabigatran in minutes.[237] Andexanet alfa, a recombinant derivative of factor Xa, was developed to reverse the factor Xa inhibitors by acting as a decoy. It has a higher affinity for factor Xa inhibitors than intrinsic factor Xa. The drug was recently approved by the FDA for patients who present with an acute hemorrhage while receiving apixaban or rivaroxaban. The indication currently does not cover edoxaban, or enoxaparin.[238,239]

EMERGING AGENTS

There are additional reversal agents in development that may be approved by the FDA soon. Ciraparantag (PER977), a small, synthetic, water-soluble, cationic molecule, binds and neutralizes UFH, LMWH, fondaparinux, dabigatran, and factor Xa inhibitors through hydrogen bonding and charge-charge interactions. Phase I trials have been completed in healthy volunteers.[240] Common anticoagulants and possible reversal agents for emergencies are listed for reference in Table 50.5.

TABLE 50.5 Common Anticoagulants Along with the Required Laboratory Monitoring and Possible Reversal Agents for Emergencies

Antithrombotic Agent	Drug Name	Stop Before Procedure	Monitoring	Reversal Agents
Antiplatelet agents	ASA P2Y12 receptor antagonists GPIIb/IIIa antagonists	7 days 7-14 days 24-72 h	None	Platelet transfusion
Vitamin K antagonists	Warfarin	2-5 days	PT, INR	PCC, FFP, vitamin K
Heparins	Unfractionated heparin (UFH)(IV)	6 h	aPTT	Protamine
	Low-molecular weight heparin (LMWH)	12-24 h	None required, but fXa levels can monitor levels	Partially reversed by protamine
Pentasaccharide	Fondaparinux	3 days (prophylactic dosing)	None required, but fXa levels can monitor levels	None
Direct thrombin inhibitors	Argatroban, Bivalirudin	4-6 h 3 h	aPTT or ACT	None
	Dabigatran	2-4 days (longer if renal impairment)	None required, thrombin time can monitor levels	Idarucizumab
FXa inhibitors	Rivaroxaban, Apixaban, Edoxaban	2-3 days 2-3 days 2-3 days	None required, but fXa levels can monitor levels	Andexanet alfa for rivaroxaban and apixaban

ACT, activated clotting time; *aPTT*, activated partial thromboplastin time; *ASA*, acetylsalicylic acid; *FFP*, fresh frozen plasma; *INR*, international normalized ratio; *IV*, intravenous; *PCC*, prothrombin complex concentrate; *PT*, prothrombin time.

Conclusion

The coagulation system remains exceedingly complex, but an understanding of the fundamental principles of hemostasis will allow the anesthesia provider to identify patients at risk of bleeding preoperatively, and safely manage blood loss and treat acquired coagulopathy both intraoperatively and postoperatively. Given the abundance of different antithrombotic and anticoagulant medications, perioperative management is becoming increasingly challenging. Early preoperative assessment of patients receiving anticoagulation and a multidisciplinary team approach between the patient, primary care physician, hematologist, surgeon, and anesthesiologist is essential to ensure the perioperative safety of these patients.

Management of the Patient with Chronic Pain

CHRISTOPH STEIN and ANDREAS KOPF

KEY POINTS

- The normal physiology of neuronal function, receptors, and ion channels is altered by persistent pain.
- Because of the large number of sources and manifestation of chronic pain, classification must include cancer-related, neuropathic, inflammatory, arthritis, and musculoskeletal pain.
- Interdisciplinary management of chronic pain must include specialists in psychology, physical therapy, occupational therapy, neurology, and anesthesiology.
- Drugs used for chronic pain are multiple and include opioids, nonsteroidal antiinflammatory drugs and antipyretic analgesics, serotonin receptor ligands, antiepileptics, antidepressants, topical analgesics (e.g., nonsteroidal antiinflammatory drugs, capsaicin, local anesthetics, opioids), and adjuvants such as local anesthetics, α_2-agonists, baclofen, botulinum toxin, antiemetics, laxatives, novel drugs such as cannabinoids, and ion channel blockers.
- Interventional management of chronic pain includes the use of diagnostic blocks, therapeutic blocks, continuous catheter techniques (peripheral, epidural, intrathecal), and stimulation techniques such as acupuncture, transcutaneous electrical nerve stimulation, and spinal cord stimulation.
- Perioperative management of patients with chronic pain involves the following: the use of opioid and nonopioid analgesics; evaluation for dependence, addiction, and pseudoaddiction; and practical considerations.

Introduction

PHYSIOLOGICAL CHANGES IN PERSISTENT PAIN

Excitatory Mechanisms

Pain may be roughly divided into two broad categories: physiologic and pathologic pain. Physiologic (acute, nociceptive) pain is an essential early warning sign that usually elicits reflex withdrawal and thereby promotes survival by protecting the organism from further injury. In contrast, pathologic (e.g., neuropathic) pain is an expression of the maladaptive operation of the nervous system; it is pain as a disease.[1] Physiologic pain is mediated by a sensory system consisting of primary afferent neurons, spinal interneurons and ascending tracts, and several supraspinal areas. Trigeminal and dorsal root ganglia (DRG) give rise to high-threshold Aδ− and C-fibers innervating peripheral tissues (skin, muscles, joints, viscera). These specialized primary afferent neurons, also called nociceptors, transduce noxious stimuli into action potentials and conduct them to the dorsal horn of the spinal cord (Fig. 51.1). When peripheral tissue is damaged, primary afferent neurons are sensitized or directly activated (or both) by a variety of thermal, mechanical, and/or chemical stimuli. Examples are protons, sympathetic amines, adenosine triphosphate (ATP), glutamate, neuropeptides (calcitonin gene-related peptide, substance P), nerve growth factor, prostanoids, bradykinin, proinflammatory cytokines, and chemokines.[2] Many of these agents lead to opening (gating) of cation channels in the neuronal membrane. Such channels include the capsaicin-, proton-, and heat-sensitive transient receptor potential vanilloid 1 (TRPV1), or the ATP-gated purinergic $P2X_3$ receptor. Gating produces an inward current of Na^+ and Ca^{++} ions into the peripheral nociceptor terminal. If this depolarizing current is sufficient to activate voltage-gated Na^+ channels (e.g., $Na_v1.8$), they too will open, further depolarizing the membrane and initiating a burst of action potentials that are then conducted along the sensory axon to the dorsal horn of the spinal cord.[2,3]

Transmission of input from nociceptors to spinal neurons that project to the brain is mediated by direct monosynaptic contact or through multiple excitatory or inhibitory interneurons. The central terminals of nociceptors contain excitatory transmitters such as glutamate, substance P, and neurotrophic factors that activate postsynaptic N-methyl-D-aspartate (NMDA), neurokinin (NK_1), and tyrosine kinase receptors, respectively. Repeated nociceptor stimulation can sensitize both peripheral and central neurons (activity-dependent plasticity). In spinal neurons such a progressive increase of output in response to persistent nociceptor excitation has been termed "wind-up." Later, sensitization can be sustained by transcriptional changes in the expression of genes coding for various neuropeptides, transmitters, ion channels, receptors, and signaling molecules (transcription-dependent plasticity) in both nociceptors and spinal neurons. Important examples include the NMDA receptor, cyclooxygenase-2 (COX-2), Ca^{++} and Na^+ channels, cytokines and chemokines expressed by neurons and/or glial cells.[2,3] In addition, physical rearrangement of neuronal

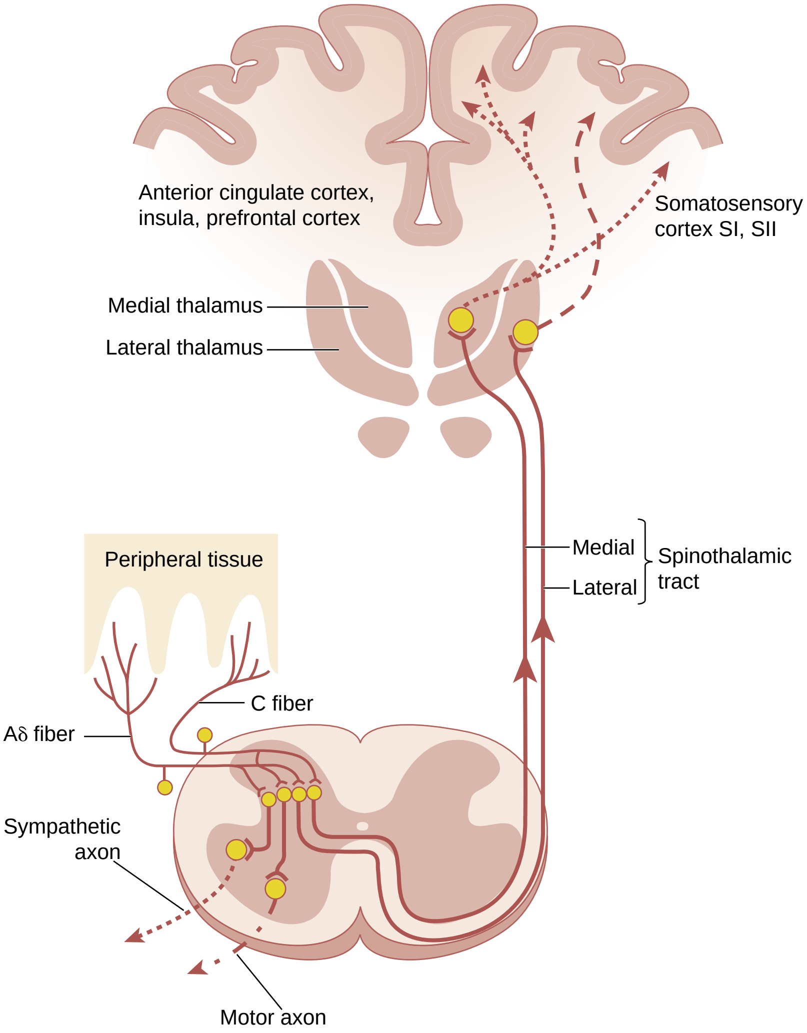

Fig. 51.1 Nociceptive pathways. For details see text. (Adapted from Brack A, Stein C, Schaible HG. Periphere und zentrale Mechanismen des Entzündungsschmerzes. In: Straub RH, ed. *Lehrbuch der klinischen Pathophysiologie komplexer chronischer Erkrankungen*. vol. 1. Göttingen Vandenhoeck & Ruprecht; 2006:183–192.[203])

circuits by apoptosis, nerve growth, and sprouting occurs in the peripheral and central nervous system.[1] Both induction and maintenance of central sensitization are critically dependent on the peripheral drive by nociceptors, indicating that therapeutic interventions targeting such neurons may be particularly effective, even in chronic pain syndromes.[3,4]

Inhibitory Mechanisms

Concurrent with the events just described, powerful endogenous mechanisms counteracting pain unfold. This was initially proposed in the "gate control theory of pain" in 1965[5] and has since been corroborated and expanded by experimental data. In 1990, a "peripheral gate" was discovered at the source of pain generation by demonstrating that immune cell-derived opioid peptides can block the excitation of nociceptors carrying opioid receptors within injured tissue[6] (Fig. 51.2). This represented the first example of many subsequently described neuro-immune interactions relevant to pain.[7-11] Inflammation of peripheral tissue leads to increased expression, axonal transport, and enhanced G-protein coupling of opioid receptors in DRG neurons as well as enhanced permeability of the perineurium. These phenomena are dependent on sensory neuron electrical activity, production of proinflammatory cytokines, and the presence of nerve growth factor within the inflamed tissue. In parallel, opioid peptide-containing immune cells extravasate and accumulate in the inflamed tissue.[9,11] These cells upregulate the gene expression of opioid precursors and the enzymatic machinery for their processing into functionally active peptides. In response to stress, catecholamines, corticotropin-releasing factor, cytokines, chemokines, or bacteria, leukocytes secrete opioids, which then activate peripheral opioid receptors and produce analgesia by inhibiting the excitability of nociceptors, the release of excitatory neuropeptides, or both (see Fig. 51.2).[9,11,12] The clinical relevance of these mechanisms has been shown in studies demonstrating that patients with knee joint inflammation express opioid peptides in immune cells and opioid receptors on sensory nerve terminals within synovial tissue.[13] After knee surgery, pain and analgesic consumption was enhanced by blocking the interaction between the endogenous opioids and their receptors with intraarticular naloxone,[14] and was diminished by stimulating opioid secretion.[15]

In the spinal cord, inhibition is mediated by the release of opioids, γ-aminobutyric acid (GABA), or glycine from interneurons, which activate presynaptic opioid- or GABA-receptors (or both) on central nociceptor terminals

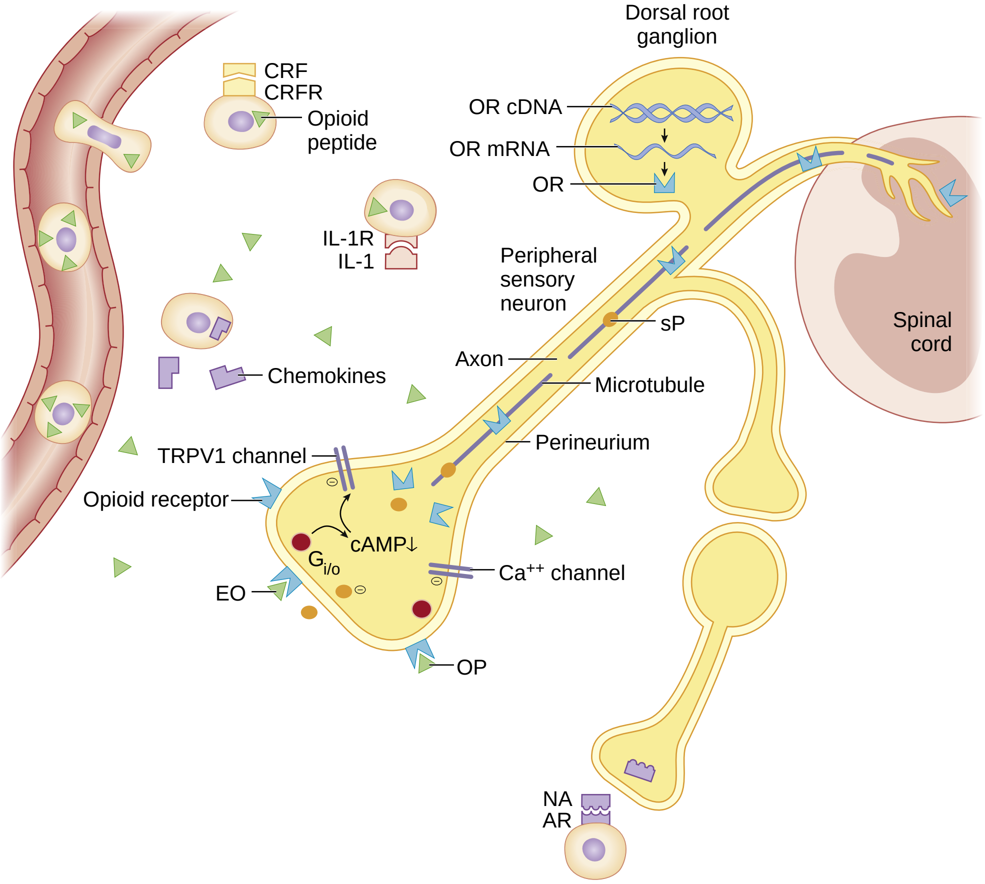

Fig. 51.2 Endogenous antinociceptive mechanisms within peripheral injured tissue. Opioid peptide–containing circulating leukocytes extravasate upon activation of adhesion molecules and chemotaxis by chemokines. Subsequently, these leukocytes are stimulated by stress or releasing agents to secrete opioid peptides. For example, corticotropin-releasing factor *(CRF)*, interleukin-1β *(IL–1)*, and noradrenaline (*NA*, released from postganglionic sympathetic neurons) can elicit opioid release by activating their respective CRF receptors *(CRFR)*, IL-1 receptors *(IL-1R)*, and adrenergic receptors *(AR)* on leukocytes. Exogenous opioids *(EO)* or endogenous opioid peptides (*OP*, green triangles) bind to opioid receptors *(OR)* that are synthesized in dorsal root ganglia and transported along intraaxonal microtubules to peripheral (and central) terminals of sensory neurons. The subsequent inhibition of ion channels (e.g., TRPV1, Ca^{++}) (see Fig. 64.3 and text) and of substance P *(sP)* release results in antinociceptive effects. (Adapted from Stein C, Machelska H. Modulation of peripheral sensory neurons by the immune system: implications for pain therapy. *Pharmacol Rev*. 2011;63:860–881.[9])

to reduce excitatory transmitter release. In addition, the opening of postsynaptic K^+ or Cl^- channels by opioids or GABA, respectively, evokes hyperpolarizing inhibitory potentials in dorsal horn neurons. During ongoing nociceptive stimulation spinal interneurons upregulate gene expression and the production of opioid peptides.[16,17] Powerful descending inhibitory pathways from the brainstem also become active by operating mostly through noradrenergic, serotonergic, and opioid systems. Key regions are the periaqueductal grey and the rostral ventromedial medulla, which then projects along the dorsolateral funiculus to the dorsal horn.[2,18] The integration of signals from excitatory and inhibitory neurotransmitters with cognitive, emotional, and environmental factors (see later) eventually results in the central perception of pain. When the intricate balance between biologic, psychological, and social factors becomes disturbed, chronic pain can develop.[19,20]

Translation of Basic Research

Basic research on pain continues at a rapid pace but translation into clinical applications has been difficult.[4,21] Many obstacles have been discussed, including overinterpretation of data, reporting bias toward neglecting negative results, inadequate animal models, flawed study design, genetic and species differences.[4,21-23] Notwithstanding, animal studies are indispensable, continue to be improved, and have successfully predicted adverse side effects of drug candidates.[22,23] For ethical reasons, many models are restricted to days or weeks, while human chronic pain can last for months or years. Therefore, animal models may be more cautiously termed as reflecting "persistent" pain.[21,23] Brain imaging is an area of intense research and numerous studies have investigated changes in patients with various pain syndromes. However, such studies have not yet provided reproducible findings specific for a disease or a pathophysiologic basis for individual syndromes.[22] Neuroimaging can only detect alterations associated with nociceptive processes whereas clinical pain encompasses a much more complex subjective experience that critically relies on self-evaluation. Thus, although recent data have provided valuable information on pain neurophysiology, current imaging techniques cannot provide an objective proxy, biomarker, or predictor for clinical pain.[24,25] Genetics is another budding scientific field. However, with the possible exception of the metabolic enzyme CYP2D6, pharmacogenetics is not expected to serve as a guide to individualized ("personalized") clinical pain therapy any time soon.[22,26-29]

CLINICAL DEFINITIONS, PREVALENCE, AND CLASSIFICATION OF CHRONIC PAIN

Definitions

The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[30] This classification further states that pain is always subjective and that it is a sensation in parts of the body. At the same time, it is unpleasant and therefore also has emotional/psychological components. Aside from malignant disease, many people report chronic pain in the absence of tissue damage or any likely pathophysiologic cause. There is usually no way to distinguish their experience from that due to tissue damage. If patients regard their experience as pain or if they report it in the same ways as pain caused by tissue damage, it should be accepted as pain.[31] Nociception is neurophysiological activity in peripheral sensory neurons (nociceptors) and higher nociceptive pathways and is defined by the IASP as the "neural process of encoding noxious stimuli." Nociception is not synonymous to pain. Chronic pain is defined as "extending in duration beyond the expected temporal boundary of tissue injury and normal healing, and adversely affecting the function or well-being of the individual" by the American Society of Anesthesiologists.[32] The IASP subcommittee on taxonomy defined it in 1986 as "pain without apparent biological value that has persisted beyond the normal tissue healing time usually taken to be three months."

Prevalence

Beyond these general definitions there exists no common understanding about the characteristics of the chronic pain patient. This may be one reason why estimates of prevalence differ greatly from one publication to another. Heterogeneous populations, the occurrence of undetected comorbidity, different definitions of chronic pain, and different approaches to data collection have resulted in estimates from 20% to 60%. Some surveys indicate a more frequent prevalence among women and the elderly. Chronic pain has enormous socioeconomic costs due to the need for healthcare services, disability compensation, lost workdays, and related expenses.[31,33,34]

Classification

There is a tradition to distinguish between malignant (related to cancer and its treatment) and nonmalignant (e.g., neuropathic, musculoskeletal, inflammatory) chronic pain. Nonmalignant chronic pain is frequently classified into inflammatory (e.g., arthritic), musculoskeletal (e.g., low back pain), headaches, and neuropathic pain (e.g., postherpetic neuralgia, phantom pain, complex regional pain syndrome, diabetic neuropathy, human immunodeficiency virus-associated neuropathy). Frequent symptoms of neuropathic pain include spontaneous lancinating, shooting, or burning pain; hyperalgesia; and allodynia.[35] Cancer pain can originate from invasion of the tumor into tissues innervated by primary afferent neurons (e.g., pleura, peritoneum) or directly into a peripheral nerve plexus. In the latter, neuropathic symptoms may be predominant. Pain may be underestimated by medical staff and family members, resulting in poor pain control.[31] Many treatments for cancer are associated with severe pain. For example, cytoreductive radiotherapy or chemotherapy frequently causes painful oral mucositis, especially in patients with bone marrow transplantation.[36]

Biopsychosocial Concept of Chronic Pain

Chronic pain is characterized by the complex interaction of biologic (tissue damage), psychological (cognition, memory, conditioning), and environmental/social factors (attention, reinforcement). Studies have shown that multimodal pain management programs rooted in this concept can lead to reduced pain, increased activity, and improved daily functioning.[37] Therefore, it is of utmost importance to screen patients with ongoing pain for risk factors. Special attention should be paid to patients presenting with limited mobility, lack of motivation, depression, anger, anxiety, and fear of reinjury, which hamper the return to normal work or recreational activities. Such patients may become preoccupied with pain and somatic processes, which may disrupt sleep and cause irritability and social withdrawal. Other cognitive factors such as patients' expectations or beliefs (e.g., perceived inability to control the pain) influence psychosocial and physical functioning. Pain behavior such as limping, medication intake, or avoidance of activity is subject to operant conditioning; that is, it responds to reward and punishment. For example, pain behavior may be positively reinforced by attention from a spouse or healthcare provider (e.g., by inadequate use of nerve blocks or medications). Conversely, such behavior can be extinguished when it is disregarded and incremental activity is reinforced by social attention and praise.[19] Respondent learning mechanisms (i.e., classical conditioning) may also contribute to chronicity.[20] Other issues often coexist, such as substance abuse problems, family dysfunction, and conflicts with legal or insurance systems. Consequently, care seeking is an integral feature of the pain experience, and excessive use of the healthcare system ensues. The interplay between these biologic, psychological, and social factors results in the persistence of pain and illness behaviors.[19,20] Treating only one aspect of this complex syndrome ("monomodal" therapy) is obviously insufficient. The biopsychosocial concept was first described by Engel in 1959[38] but its implementation into daily practice has been tardy, especially concerning chronic pain patients.[39,40] This concept helps to understand why chronic pain may exist without obvious physical cause or why pathologic somatic findings may remain unnoticed by the patient. Interestingly, the experience and regulation of social and physical pain may share a common neuroanatomic basis.[41] In a multimodal approach, pain management simultaneously addresses physical, psychological, and social skills and underscores the patients' active responsibility to regain control over life by improving function and well-being.[20,37,42] Methods usually include (among others) cognitive-behavioral therapy, physical exercise, and medication management. Cognitive-behavioral therapy aims to correct maladaptive cognitive and behavioral patterns, such as catastrophizing and fear-avoidance-beliefs. It encourages patients to take a proactive versus passive role in their healing process, and to experience life mindfully through defusion, acceptance, and committed action.[43,44] Functional restoration includes occupational and physical therapy to help the patient gain confidence in physical activity. Activation per se seems to be more important than specific therapeutic techniques. Social support can affect pain intensity and mood by addressing employment and retirement issues as well as other concerns such as financial and legal disputes.

INTERDISCIPLINARY MANAGEMENT OF CHRONIC PAIN

The anesthesiologist John J. Bonica was the first to appreciate the need for a multidisciplinary approach to chronic pain. His early experiences in and after World War II convinced Bonica that complex pain problems could be more effectively treated when different disciplines contribute their specialized knowledge and skills to the common goal of making a correct diagnosis and developing the most effective therapeutic strategy. The first multidisciplinary facility was put into practice at the Tacoma General Hospital, followed by the University of Washington in 1960. From 1970 through 1990, the number of pain management facilities continued to increase in North America and Europe, mostly directed by anesthesiologists. Such comprehensive pain centers should have personnel and facilities to evaluate and treat the biomedical, psychosocial, and occupational aspects of chronic pain and to educate and teach medical students, residents, and fellows. Guidelines for characteristics of pain treatment facilities have been published by the IASP.[45] Interdisciplinary and multimodal management results in increased physical and psychosocial function, reduced health care use, and vocational rehabilitation. Such programs offer the most efficacious and cost-effective, evidence-based treatment of chronic nonmalignant pain.[37,40] Treatment without an interdisciplinary approach is inadequate and may lead to misdiagnoses. For example, overlooking psychological processes in a presumed discogenic back pain, or overlooking a somatic etiology in a presumed "psychogenic" pain disorder may lead to the wrong conclusions.[46] Moreover, conventional monomodal approaches such as pharmacotherapy alone only perpetuate the expensive, futile, and endless search for medical solutions.[40,42]. A prominent example is the recent "opioid epidemic" with inadequate opioid medication as a monomodal therapy of chronic noncancer pain, which has significantly delayed appropriate diagnostic and therapeutic management.[47] The "current opioid misuse measure" questionnaire may be a useful tool to detect inadequate opioid medication.[48]

The core team usually comprises a pain management physician (often an anesthesiologist with subspecialty training but could also be a physical medicine and rehabilitation physician or psychiatrist with appropriate training), a psychologist, a physical therapist, and an occupational therapist. Depending on the local circumstances, administrators, social workers, pain nurses, and/ or pharmacists can also be involved. The initial screening of the patient by members of the core team determines what other specialists will be needed for a complete assessment. After this evaluation, the patient is presented to the entire core team and a comprehensive treatment plan is developed. This plan is tailored to the patient's needs, abilities, and expectations, with a focus on achieving measurable treatment goals established with the patient. For some patients, education and medical management may suffice, whereas for others, an intensive full-day outpatient or inpatient rehabilitation program over several weeks may be needed. Early stratification of the management according to the patient's prognosis (low, medium, or high risk for persistent disability because of pain) results in significantly higher clinical and cost effectiveness.[49] To foster patient compliance, an open discussion of treatment goals with regard to the patient's expectations is essential. Many patients expect the complete resolution of pain and the return to full function, a goal that may not be achievable. More realistic options are some reduction of pain, improvement of physical function, and/or return to work. Mood, sleep, active coping skills, and social functioning may also be improved.[50,51] Thus, rehabilitation rather than cure is the most appropriate therapeutic option.[40]

Psychology

The role of the psychologist includes the initial assessment and treatment approaches such as education, cognitive-behavioral therapy, and relaxation training. Assessment of the patient addresses the sensory, affective, cognitive, behavioral, and occupational dimensions of the pain problem. This includes an extensive biographic history and behavioral analysis along with the use of questionnaires. Most questionnaires include scoring systems for pain intensity (e.g., numerical or visual analog scales), but pain behavior (e.g., West-Haven-Yale Multidimensional Pain Inventory), multidimensional pain quality, cognitive coping, fear (e.g., State-Trait-Anxiety-Inventory), depression, and other associated symptoms are far more relevant. Indications for psychological pain management are relevant somatization, depressive disorders, inadequate coping, drug abuse, and high levels of pain behavior reinforced by the environment (e.g., family members). A key factor is motivational change for acceptance of the complex therapeutic program.[52] Some types of pain syndromes, such as chronic headache, inflammatory rheumatic pain, or unspecific back pain may specifically benefit from behavioral therapy.[20,40] This usually means a complete change of view for the patient, from a purely passive recipient of curative treatment to an active, self-reliant approach to functional restoration, vocational rehabilitation, and reduced healthcare use despite pain. Thus, pain reduction alone is no longer the focus of therapy.[37,40]

Physical Therapy

The role of the physical therapist includes initial evaluation of the musculoskeletal system, assessment of the patient's workplace and home, education in active physical coping skills, and management of the physical rehabilitation process. An intensive exercise program emphasizing the patient's responsibility for self-management is an integral part of comprehensive programs for chronic nonmalignant pain.[37,40,53] Improving fitness, mobility, and posture counteracts the effects of disuse and complements behavioral treatment. The physical therapist encourages the adoption of regular exercise into daily life, facilitates repeated exposure to movement as much as possible despite pain, and reinforces education in the biopsychosocial model of pain management. Different techniques of exercise such as muscle conditioning and aerobics are efficacious in improving function, pain, disability, and fear avoidance behavior.[54,55] On the other hand, passive treatments like massage or chiropractic interventions are not beneficial.[56] The regimen of graded exercise follows the original concept of Fordyce.[19] Patients are instructed to find a baseline tolerance level for each exercise. Next, a program of improvement is negotiated and agreed upon. Patients note improvements on a daily basis and are required to complete the exercise plan regardless of how they feel. Thus, the control over exercise behavior is contingent upon plan rather than pain, since exercise and pain are disconnected. Individual motivation is an important factor determining how well patients learn to manage pain.[57]

Occupational Therapy

The occupational therapist teaches the patient to achieve life goals despite pain and to overcome the limitations imposed by pain. Occupational therapy assessment includes a history of working life and place, family life, and daily activities, as well as a physical examination to determine range-of-motion and the presence of movement disorders or deformities that might hinder performance. The primary therapeutic objectives are reduction of pain and associated disability, promotion of optimal function in everyday life, and the encouragement of meaningful family, social, and work relationships.[58] An important target is supporting the patient's return to work including specific work conditioning.[59] The chance of returning to work after a period of sick leave from low back pain, for example, apparently decreases over time, thereby generating enormous cost to society through wage compensation, social support, and loss of production.[31] Barriers to return to work include job dissatisfaction and perceptions of the impact of work on the cause of pain. Together with the patient, the occupational therapist should develop a program to increase self-esteem, restore self-efficacy, and promote optimal occupational and recreational function despite pain.

Anesthesiology

The role of the anesthesiologist in the treatment of chronic pain has changed considerably over the last decades. "Nerve block practices" have been replaced by interdisciplinary pain management centers. In this context the anesthesiologist acts as both a physician-educator and a technical expert. The challenge is to optimally complement regional anesthesia skills and pharmacologic knowledge with the psychosocial components of chronic pain to render more comprehensive pain management services. Anesthesiologists need to use their expertise in pharmacotherapy, nerve blocks, and skilled techniques within the broad-based biopsychosocial approach. The focus is not only on reducing pain but also on decreasing disability, improving quality of life, and increasing function. The conventional way of administering medication "as needed" or to use nerve blocks for short-term pain relief may risk reinforcement of pain behavior, and the patient's belief in an underlying physical abnormality that is best managed by biomedical procedures.[42] Moreover, false expectations are maintained; for example, the patient cannot be the passive recipient, but must be an active participant in the process. Patients may believe that pain is the primary problem in the patient's life. This neglects psychosocial factors, perpetuates the expensive and futile search for unidimensional biomedical solutions, and promotes iatrogenic somatization, medicalization, and high health care use by chronic pain patients.[42] The role of the anesthesiologist within the interdisciplinary team differs depending on the type of patient being treated. Cancer and acute pain management demand the full range of the anesthesiologist's technical skills and pharmacologic knowledge. In chronic nonmalignant pain, the anesthesiologist's abilities as an educator, coach, and motivator are far more important. As a member of the interdisciplinary team, the anesthesiologist has to reinforce and maintain the biopsychosocial focus, respond appropriately to somatic concerns, and manage medications. In concert with the other members of the team, the anesthesiologist uses motivational strategies to encourage the patient to attain self-managed reactivation goals in physical, psychosocial, recreational, and vocational domains. At the same time, the anesthesiologist's presence provides "white coat credibility" and is essential to avoid the patient's pejorative conclusion that the pain is "all in my head." The anesthesiologist monitors the patient's physical status, potential development of new medical problems, and medications. In addition, the anesthesiologist provides real-time reassurance and education regarding the absence of relevant abnormality, the minimal role of surgery, and conveys medical information to make informed choices. The anesthesiologist plays a crucial role within the multidisciplinary team to direct the patient toward a multimodal pain treatment plan and to coordinate this program. The majority of pain therapists worldwide are anesthesiologists. They work closely with other healthcare professionals in this setting, thereby gaining added recognition outside the operating room.[42]

Drugs Used for Chronic Pain

Analgesic drugs interfere with the generation or transmission (or both) of impulses following noxious stimulation in the nervous system (nociception). This can occur at both the peripheral and central levels of the neuraxis. The therapeutic aim is to diminish the perception of pain. Analgesics aim at modulating either the formation of noxious chemicals (e.g., prostaglandins) or the activation of neuronal receptors or ion channels transducing or transmitting noxious stimuli (e.g., peptide, kinin, monoamine receptors, Na^+ channels). Drugs currently used in chronic pain include opioids, nonsteroidal antiinflammatory drugs (NSAIDs), serotonergic compounds, antiepileptics, and antidepressants (Table 51.1). Local anesthetics are used for local and regional anesthetic techniques. Mixed drugs combine different mechanisms, for example noradrenaline reuptake inhibition and opioid agonist effects (tramadol, tapentadol), or opioid agonist and NMDA antagonist effects (ketamine). Various routes of drug administration (e.g., oral, intravenous, subcutaneous, intrathecal, epidural, topical, intraarticular, transmucosal) can be used, depending on the clinical circumstances. In addition, placebo treatments have shown significant analgesic effects, mediated by opioid and nonopioid mechanisms.[60] Chronic pain requires a multidisciplinary approach encompassing both pharmacologic and nonpharmacologic (psychological, physiotherapeutic) treatment strategies (see "Interdisciplinary Management of Chronic Pain").

TABLE 51.1 Analgesic Drugs, Targets, Mechanisms, and Side Effects

Drugs	Targets	Mechanisms	Functional Consequences	Side Effects
Opioids	G-protein coupled μ-, δ-, κ-receptors	↓ cAMP ↓ Ca^{++} currents ↑ K$^+$ currents	↓ Excitability of peripheral and central neurons ↓ Release of excitatory neurotransmitters	μ, δ: sedation, nausea, euphoria/reward, respiratory depression, constipation κ: dysphoria/aversion, diuresis, sedation
NSAIDs	cyclooxygenases (COX-1, COX-2)	↓ prostaglandins ↓ thromboxanes	↓ Sensitization of sensory neurons ↑ Inhibition of spinal neurons	Nonselective: gastrointestinal ulcers, perforation, bleeding, renal impairment COX-2: thrombosis, myocardial infarction, stroke
Serotonin agonists	G-protein coupled 5-HT receptors 5-HT$_3$: ion channels	↓ cAMP (5-HT$_1$) ↑ cAMP (5-HT$_{4-7}$) ↑ PLC (5-HT$_2$)	↓ Release of excitatory neuropeptides ↓ Neurogenic inflammation ↑ Vasoconstriction	Myocardial infarction, stroke, peripheral vascular occlusion
Antiepileptics	Na$^+$, Ca^{++} channels GABA receptors	↓ Na$^+$ currents ↓ Ca^{++} currents ↑ GABA receptor activity	↓ Excitability of peripheral and central neurons ↓ Release of excitatory neurotransmitters	Sedation, dizziness, cognitive impairment, ataxia, hepatotoxicity, thrombocytopenia
Antidepressants	Noradrenaline/5-HT transporters Na$^+$, K$^+$ channels	↓ Noradrenaline/5-HT reuptake ↓ Na$^+$ currents ↑ K$^+$ currents	↓ Excitability of peripheral and central neurons	Cardiac arrhythmia, myocardial infarction, sedation, nausea, dry mouth, constipation, dizziness, sleep disturbance, blurred vision

NSAIDs, Nonsteroidal antiinflammatory drugs; *GABA*, γ-aminobutyric acid (GABA).

OPIOIDS

Opioids act on heptahelical G-protein-coupled receptors. Three types of opioid receptors (μ, δ, κ) have been cloned. Several subtypes (e.g., μ_1, μ_2, δ_1, δ_2), possibly resulting from gene polymorphisms, splice variants, or alternative processing have been proposed. Opioid receptors are localized and can be activated along all levels of the neuraxis including peripheral and central processes of primary sensory neurons (nociceptors), spinal cord (interneurons, projection neurons), brainstem, midbrain, and cortex. All opioid receptors couple to G-proteins (mainly G_i/G_o) and subsequently inhibit adenylyl cyclase, decrease the conductance of voltage-gated Ca^{++} channels, or open rectifying K$^+$ channels, or any combination of these actions (Fig. 51.3*a*).[61] These effects ultimately result in decreased neuronal activity. The prevention of Ca^{++} influx inhibits the release of excitatory (pronociceptive) neurotransmitters. A prominent example is the suppression of substance P release from primary sensory neurons, both within the spinal cord and from their peripheral terminals within injured tissue. At the postsynaptic membrane, opioids produce hyperpolarization by opening K$^+$ channels, thereby preventing excitation or propagation of action potentials in second-order projection neurons. In addition, opioids inhibit sensory neuron-specific tetrodotoxin-resistant Na$^+$ channels, TRPV1 channels, and excitatory postsynaptic currents evoked by glutamate receptors (e.g., NMDA) in the spinal cord. The result is decreased transmission of nociceptive stimuli at all levels of the neuraxis and profoundly reduced perception of pain. Endogenous opioid receptor ligands are derived from the precursors proopiomelanocortin (encoding β-endorphin), proenkephalin (encoding Met-enkephalin and Leu-enkephalin), and prodynorphin (encoding dynorphins). These peptides contain the common Tyr-Gly-Gly-Phe-Met/Leu sequence at their amino terminals, known as the opioid motif. β-Endorphin and the enkephalins are potent antinociceptive agents acting at μ− and δ−receptors. Dynorphins can elicit both pro- and antinociceptive effects via NMDA receptors and κ−opioid receptors, respectively. A fourth group of tetrapeptides (endomorphins) with yet unknown precursors do not contain the pan-opioid motif but bind to μ−receptors with high selectivity. Opioid peptides and receptors are expressed throughout the central and peripheral nervous system, in neuroendocrine tissues, and in immune cells.[9,62] Extracellular opioid peptides are susceptible to rapid enzymatic inactivation by aminopeptidase N and neutral endopeptidase. Both peptidases are expressed in the central nervous system, peripheral nerves, and leukocytes and, among opioids, enkephalins are considered their preferred substrates. Preventing the extracellular degradation of endogenous opioid peptides by peptidase inhibitors, both in central and peripheral compartments, has been shown to produce potent analgesic effects in many animal models and in some small human trials.[63,64]

The commonly available opioid drugs (morphine, codeine, methadone, fentanyl and its derivatives) are μ−agonists. Naloxone is a nonselective antagonist at all three receptors. Partial agonists must occupy a greater fraction of the available pool of functional receptors than full agonists to induce a response of equivalent magnitude. Mixed agonist/antagonists (buprenorphine, butorphanol, nalbuphine, pentazocine) may act as agonists at low doses and as antagonists (at the same or a different receptor type) at higher doses. Such compounds typically exhibit ceiling effects for analgesia and they may elicit an acute withdrawal syndrome when administered together with a pure agonist. All three receptors (μ, δ, κ) mediate analgesia but differing side effects. μ-Receptors mediate respiratory depression, sedation, reward/euphoria, nausea, urinary retention, biliary spasm, and constipation. κ-Receptors mediate dysphoric, aversive, sedative, and diuretic effects. δ-Receptors mediate reward/euphoria, respiratory depression, convulsions,

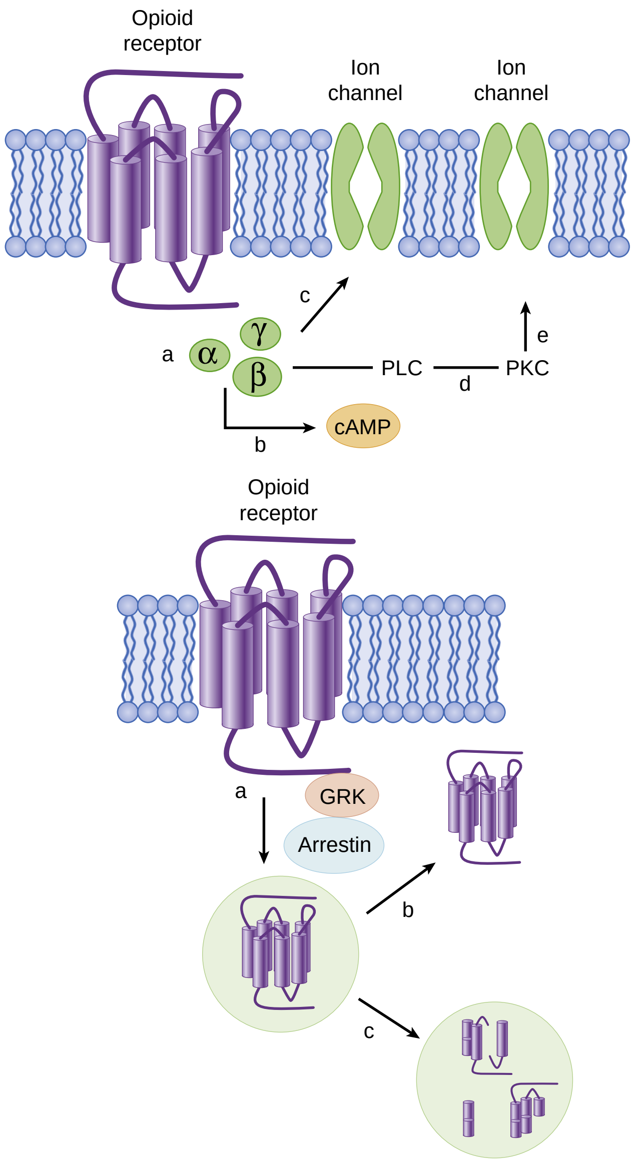

Fig. 51.3 Opioid receptor signaling and recycling. Upper panel: Opioid ligands induce a conformational change at the receptor which allows coupling of G proteins to the receptor. The heterotrimeric G-protein dissociates into active G_{α} and $G_{\beta\gamma}$ subunits (a) which can inhibit adenylyl cyclase and reduce *cAMP* (b), decrease the conductance of voltage-gated Ca^{++} channels, or open rectifying K^{+} channels (c). In addition, the phospholipase C/phosphokinase C pathways can be activated (d) to modulate Ca^{++} channel activity in the plasma membrane (e). Lower panel: Opioid receptor desensitization and trafficking is activated by G protein-coupled receptor kinases *(GRK)*. After arrestin binding, the receptor is in a desensitized state at the plasma membrane (a). Arrestin-bound receptors can then be internalized via a clathrin-dependent pathway, and either be recycled to the cell surface (b) or degraded in lysosomes (c). (Adapted from Zöllner C, Stein C. Opioids. *Handb Exp Pharmacol*. 2007;(177):31–63.[204])

and constipation.[65-67] Immunosuppressive effects of opioids were frequently proposed in experimental studies but have not been verified in clinical outcome trials.[68,69]

Tolerance describes the phenomenon that the magnitude of a given drug effect decreases with repeated administration of the same dose, or that increasing doses are needed to produce the same effect. Tolerance is not synonymous with dependence. Physical dependence is defined as a state of adaptation that is manifested by a withdrawal syndrome elicited by abrupt cessation, rapid dose reduction, and/or administration of an antagonist.[70] All opioids produce clinically relevant physical dependence, even when administered only for a relatively short period of time.[71] All opioid effects (e.g., analgesia, nausea, respiratory depression, sedation, constipation) can be subject to tolerance development, albeit to different degrees. For example, tolerance to respiratory depression, sedation, and nausea often develops faster than to constipation or miosis.[66,67,72,73] Incomplete cross-tolerance between opioids or genetic differences may explain clinical observations that switching drugs ("opioid rotation") is occasionally useful in patients with inadequate pain relief or intolerable side effects.[74] Opioid-induced adaptations occur at multiple levels in the nervous and other organ systems, beginning with direct modulation of opioid receptor signaling and extending to complex neuronal networks including learned behavior. Proposed mechanisms involved in pharmacodynamic tolerance include opioid receptor-G-protein uncoupling, decreased receptor internalization/recycling, and increased sensitivity of the NMDA receptor (see Fig. 51.3*b*).[61] In addition, pharmacokinetic (e.g., altered distribution or metabolism of the opioid) and learned tolerance (e.g., compensatory skills developed during mild intoxication) as well as increased nociceptive stimulation by tumor growth, inflammation, or neuroma formation are possible reasons for increased dose requirements.[72,75] There is a lack of carefully controlled studies that unequivocally demonstrate pharmacodynamic tolerance to opioid analgesia (i.e., reduction of clinical pain) in patients.[76,77]

There is an ongoing debate whether opioids may paradoxically induce hyperalgesia. However, many studies have, in fact, shown withdrawal-induced hyperalgesia, a well-known phenomenon following the abrupt cessation of opioids.[78-80] At high doses, occasionally encountered in extreme cancer pain, singular cases of allodynia have been observed and attributed to neuroexcitatory effects of opioid metabolites.[81] There is no conclusive evidence that hyperalgesia occurs during the perioperative or chronic administration of regular opioid doses in patients.[77,78,82,83]

Opioids are effective in the periphery (e.g., topical or intraarticular administration, particularly in inflamed tissue), at the neuraxis (intrathecal, epidural, or intracerebroventricular administration), and systemically (intravenous, oral, subcutaneous, sublingual, or transdermal administration).[18] The clinical choice of a particular compound or its formulation is based on pharmacokinetic considerations (route of administration, desired onset or duration, lipophilicity) and on side effects associated with the respective route of drug delivery.[18] Dosages are dependent on patient characteristics, type of pain, and route of administration. Systemically and spinally administered opioids can produce similar side effects, depending on dosage and rostral/systemic redistribution. For intrathecal application lipophilic drugs are preferred because they are trapped in the spinal cord and less likely to migrate to the brain within the cerebrospinal fluid. Adverse side effects can be minimized by careful dose titration and close patient monitoring, or can be treated by co-medication (antiemetics, laxatives) or opioid receptor antagonists (e.g., naloxone). No significant side effects have been reported for the peripheral (e.g., topical) application of small, systemically inactive doses of opioids.

Opioids are considered the most effective analgesics for severe acute (e.g., postoperative) and cancer-related chronic pain. However, the long-term use of opioids in chronic noncancer (e.g., neuropathic, musculoskeletal, abdominal) pain is highly controversial. Randomized controlled trials (RCTs) have only been conducted for a maximum period of 3 months. In meta-analyses, the reduction of pain scores was clinically insignificant and epidemiological data suggest that quality of life or functional capacity are not improved.[84-86] A recent meta-analysis of RCTs of patients with chronic noncancer pain, evidence from high-quality studies showed that opioid use was associated with statistically significant but small improvements in pain and physical functioning, and increased risk of vomiting compared with placebo.[86a] In this meta-analysis comparisons of opioids with nonopioid alternatives suggested that the benefit for pain and functioning may be similar, although the evidence was from studies of only low to moderate quality. Adverse side effects (nausea, sedation, constipation, dizziness, etc.) and lack of analgesic efficacy led to the dropout of high numbers of subjects, both in RCTs and in uncontrolled observational studies beyond 3 months.[86] Psychosocial outcome variables were rarely investigated and showed only modest improvement. Thus, consistent with the multifactorial nature of chronic pain, opioids alone probably cannot produce an analgesic response. Clearly, the entire patient must be evaluated, not just the pain.[87] The target of intervention is not only the source of nociception (if at all identifiable) but suffering, dysfunction, psychosocial factors, and dependence on the healthcare system. In addition, addiction has been reported in high numbers of patients treated with opioids for chronic pain, and overdoses, death rates, and abuse of prescription opioids have become a public health problem.[84,88] Thus, the use of opioids as a sole treatment modality in chronic nonmalignant pain is strongly discouraged.[47]

NONSTEROIDAL ANTIINFLAMMATORY DRUGS AND ANTIPYRETIC ANALGESICS

NSAIDs and antipyretic analgesics (e.g., acetaminophen, phenazones) inhibit COX, the enzymes that catalyze the transformation of arachidonic acid (a ubiquitous cell component generated from phospholipids) to prostaglandins and thromboxanes.[89] Two isoforms, COX-1 and COX-2, are constitutively expressed in peripheral tissues and in the central nervous system. In response to injury and inflammatory mediators (e.g., cytokines, growth factors) both isoforms can be upregulated, resulting in increased concentrations of prostanoids. In the periphery, prostanoids (mainly PGE_2) sensitize nociceptors by phosphorylation of ion channels (e.g., Na^+, TRPV1) via EP receptor activation. As a result, nociceptors become more responsive to noxious mechanical (e.g., pressure, hollow organ distension), chemical (e.g., acidosis, bradykinin, neurotrophic factors), or thermal stimuli. In the spinal cord PGE_2 blocks glycinergic neuronal inhibition, enhances excitatory amino acid release, and depolarizes ascending neurons. These mechanisms facilitate the generation of impulses within nociceptors and their transmission through the spinal cord to higher brain areas. By blocking COX, prostanoid formation diminishes. Subsequently, nociceptors become less responsive to noxious stimuli and spinal neurotransmission is attenuated.

Less severe pain states (e.g., early arthritis, headache) are commonly treated with nonselective NSAIDs (e.g., aspirin, ibuprofen, indomethacin, diclofenac) or antipyretic analgesics (e.g., acetaminophen), mostly used orally. Some drugs are available for parenteral, rectal, or topical application. Over-the-counter availability and self-medication have led to frequent abuse and toxicity.[89] Adverse side effects are attributed to COX-1-induced blockade of thromboxane production and impairment of platelet function (gastrointestinal and other bleeding disorders), decrease of tissue-protective prostanoids (gastrointestinal ulcers, perforation), decrease of renal vasodilatory prostanoids (nephrotoxicity), and to formation of highly reactive metabolites (acetaminophen hepatotoxicity). The development of selective COX-2 inhibitors was driven by the assumption that COX-2 expression is selectively induced in inflamed tissue and that the constitutive tissue-protective COX-1 would be spared. It has now become clear that COX-2 expression is constitutive in many tissues (e.g., gastrointestinal epithelium, vascular endothelium, spinal cord) and COX-2 inhibition may exacerbate inflammation, impair ulcer healing, and decrease formation of vasoprotective prostacyclin. COX inhibitors confer an increased risk of thrombosis, myocardial infarction, renal impairment, hypertension, stroke, and liver toxicity, and can cause rare anaphylactic reactions.

NSAIDs and antipyretic analgesics play a controversial role in chronic pain. For example, their uncontrolled use may result in medication overuse headache.[90] In chronic degenerative musculoskeletal pain, their use is disputed[91] and they are not indicated in neuropathic pain.[92]

SEROTONERGIC DRUGS

Serotonin (5-hydroxytryptamine; 5-HT) is a monoamine neurotransmitter found in the sympathetic nervous system, in the gastrointestinal tract, and in platelets. It acts on 5-HT receptors expressed at all levels of the neuraxis and on blood vessels. Within the dorsal horn of the spinal cord serotoninergic neurons contribute to endogenous pain inhibition. With the exception of 5-HT_3 (a ligand-gated ion channel), 5-HT receptors are G-protein coupled receptors. 5-$HT_{1B/1D}$ agonists (triptans) have been studied extensively and are effective against neurovascular (migraine, cluster) headaches. Migraine is thought to be related to the release of neuropeptides (e.g., calcitonin gene-related peptide) from trigeminal sensory neurons innervating meningeal and intracranial blood vessels. This leads to vasodilation, an inflammatory reaction, and subsequent pain. Triptans inhibit neurogenic inflammation via 5-HT_{1D} receptors on trigeminal afferents, with possible additional sites of action on thalamic neurons and in the periaqueductal grey. The activation of vascular 5-HT_{1B} receptors constricts meningeal (and coronary) vessels. The latter effects have stimulated a search for alternative approaches such as targeting calcitonin-gene-related-peptide or highly selective 5HT_{1F} agonists.[93] Triptans can be applied orally, subcutaneously, or transnasally and have been used in the treatment of migraine. All triptans narrow coronary arteries via 5-HT_{1B} receptors at clinical doses and should not be administered to patients with risk factors or coronary, cerebrovascular, or peripheral vascular disease. Many compounds have the potential for significant drug-drug interactions.[93]

ANTIEPILEPTIC DRUGS

Antiepileptics are used in neuropathic pain resulting from lesions to the peripheral (e.g., diabetes, herpes) or central (e.g., stroke) nervous system and for migraine prophylaxis. Neuropathic syndromes have been attributed to ectopic activity in sensitized nociceptors from regenerating nerve sprouts, recruitment of previously "silent" nociceptors, or spontaneous neuronal activity (or any combination of these processes). These events may result in sensitization of primary afferents and subsequent sensitization of second- and third-order ascending neurons. Among the best studied mechanisms are the increased expression and trafficking of ion channels (e.g., Na^+, Ca^{++}, TRP) and increased activity at glutamate (NMDA) receptor sites. The mechanisms of action of antiepileptics include neuronal membrane stabilization by blockage of pathologically active voltage-sensitive Na^+ channels (e.g., carbamazepine, lamotrigine, topiramate), blockage of voltage-dependent Ca^{++} channels (gabapentin, pregabalin), inhibition of presynaptic release of excitatory neurotransmitters (gabapentin, lamotrigine), and enhancing the activity of GABA receptors (topiramate). The most common adverse effects are impaired mental (somnolence, dizziness, cognitive impairment, fatigue) and motor (ataxia) function, which limit clinical use, particularly in elderly patients. Other serious side effects have been reported, including hepatotoxicity, thrombocytopenia, dermatologic and hematologic reactions.[94] Specific indications include trigeminal neuralgia for sodium- and diabetic neuropathy for calcium-channel blockers.[95]

ANTIDEPRESSANTS

Antidepressants are used in the treatment of neuropathic pain and headache. They are divided into nonselective noradrenaline/5-HT reuptake inhibitors (amitriptyline, imipramine, clomipramine, duloxetine, venlafaxine), preferential noradrenaline reuptake inhibitors (desipramine), and selective 5-HT reuptake inhibitors (citalopram, fluoxetine). The reuptake block leads to a stimulation of endogenous monoaminergic pain inhibition in the spinal cord and brain. Tricyclic antidepressants also have NMDA receptor antagonist, endogenous opioid enhancing, Na^+ channel blocking, and K^+ channel opening effects, which can suppress peripheral and central sensitization. Block of cardiac ion channels by tricyclics can lead to arrhythmias. In patients with ischemic heart disease, there may be increased risk of sudden arrhythmia, and in patients with recent myocardial infarction, arrhythmia, or cardiac decompensation tricyclics should not be used at all. Tricyclics also block histamine, cholinergic, and adrenergic receptor sites. Adverse events of antidepressants include sedation, nausea, dry mouth, constipation, dizziness, sleep disturbance, and blurred vision.[94]

TOPICAL ANALGESICS

The topical application of various analgesics is an area of considerable interest because many chronic pain syndromes depend on the peripheral activation of primary afferent neurons.[3,4] The localized administration can potentially optimize drug concentrations at the site of pain generation, while avoiding high plasma levels, systemic side effects, drug interactions, and the need to titrate doses into a therapeutic range. Studies have demonstrated effectiveness for topical NSAIDs, tricyclic antidepressants, capsaicin, local anesthetics, and opioids.[4,94,96,97]

Topical NSAIDs are typical over-the-counter medications, widely advertised and used for acute and chronic pain. A large number of formulations (cream, gel, ointment) are commercially available. Meta-analyses concluded that topical NSAIDs have limited efficacy in chronic musculoskeletal pain.[96] Topically applied capsaicin interacts with nociceptive neurons via the TRPV1 receptor. It causes an initial activation of these neurons with release of substance P. This is perceived as a burning or itching sensation with a flare response and occurs in a high number of patients.[96] After repeated application desensitization occurs, probably due to depleting sensory neurons of substance P. Another potential mechanism is a direct toxic effect on small-diameter sensory nerve fibers. Topical capsaicin was shown to provide pain relief in postherpetic neuralgia, postmastectomy syndrome, osteoarthritis, and a variety of neuropathic syndromes.[98]

Topical formulations of local anesthetics block Na^+ channels in primary afferent neurons. Blockade of Na^+ channels reduces impulse generation both in normal and in damaged sensory neurons. Such neurons exhibit spontaneous and ectopic firing, possibly contributing to certain conditions of chronic neuropathic pain. Under these conditions the altered expression, distribution, and function of ion channels along axons is associated with increased sensitivity to local anesthetics. Thus, pain relief may be achieved with local anesthetic concentrations lower than those that totally block impulse conduction.[99] Some studies using lidocaine patches and gels showed reduction of allodynia in postherpetic neuralgia and other types of neuropathic pain.[96]

Topically applied or locally injected opioids produce analgesia by activating opioid receptors on primary afferent neurons. This leads to inhibition of Ca^{++}, Na^+, and TRPV1 currents, which are activated by inflammatory agents.[9,62] Subsequently the excitability of nociceptors, the propagation of action potentials, and the release of proinflammatory neuropeptides (substance P) from sensory nerve endings are inhibited. All of these mechanisms result in analgesia or antiinflammatory effects (or both).[9,100] Other mechanisms accounting for the particular efficacy of peripheral opioids in pain associated with inflammation include upregulation[101] and accelerated centrifugal transport of opioid receptors in sensory neurons,[102] enhanced G-protein coupling of peripheral opioid receptors,[103] and disruption of the perineural barrier facilitating access of opioid agonists to their receptors.[104,105] Consistently, the perineural application of opioids along uninjured nerves (e.g., axillary plexus) does not reliably produce analgesic effects.[106] In addition, the production and secretion of endogenous opioid peptides from immune cells within injured tissue[10,107] appears to produce additive/synergistic interactions[108] rather than tolerance at peripheral opioid receptors.[109] Peripheral opioid administration is regularly used and well documented in the case of perioperative intraarticular morphine.[110-111] Intraarticular morphine also produces analgesia in chronic rheumatoid and osteoarthritis where its effect was shown to be similarly potent to standard intraarticular steroids and long lasting, possibly due to morphine's antiinflammatory activity.[9,100] In numerous small studies, locally applied opioids (e.g., in gels) have shown analgesic efficacy in the treatment of skin ulcers, cystitis, cancer-related oral mucositis, corneal abrasion, and bone injury. No significant adverse effects have been reported.[97]

OTHER ANALGESICS AND ADJUVANTS

Local anesthetics have been used orally, intravenously, in trigger-point injections, and in regional anesthetic techniques for selected chronic pain syndromes (see later under "Interventional Methods Used in Chronic Pain" and other chapters on "local anesthetics"). Their systemic application exhibited mixed success in various neuropathies. Meta-analyses indicate that local anesthetics produce moderate analgesic effects of questionable clinical significance in neuropathic pain.[94] Severe side effects including arrhythmias, dizziness, nausea, and fatigue limit the systemic application of local anesthetics.

α_2-Adrenergic receptors are G-protein coupled and, similar to opioids, α_2-agonists (clonidine) lead to opening of K^+ channels, inhibition of presynaptic Ca^{++} channels, and inhibition of adenylyl cyclase. Thus, like opioids, α_2-agonists reduce neurotransmitter release and decrease postsynaptic transmission, resulting in an overall inhibitory effect.[112] Clonidine may exert analgesic effects in some neuropathic pain syndromes.[94] However, its systemic use is limited by sedation, hypotension, and bradycardia.

Cannabinoids have been studied extensively and are currently in the focus of public interest. Animal and in vitro models have shown that derivatives of tetrahydrocannabinol produce antinociceptive effects and that cannabinoid receptors and their endogenous ligands are expressed in pain-processing areas of the brain, spinal cord, and periphery. Peripheral cannabinoid receptors likely play a prominent role in pain inhibition.[9] Meta-analyses of human studies concluded that the analgesic effects of cannabinoids are modest, not superior to those of other analgesics, and of questionable clinical significance. Psychotropic side effects, sedation, dizziness, cognitive impairment, nausea, dry mouth, and motor deficits are limiting factors in clinical practice.[113,114]

Drugs reducing muscle spasm (e.g., benzodiazepines, baclofen) are often used in musculoskeletal pain but the available evidence does not indicate lasting beneficial effects while drowsiness and dizziness are frequently encountered.[115] Baclofen activates GABA-B receptors presynaptically and postsynaptically, leading to a decrease in excitatory and an increase in inhibitory neurotransmission. In some reports it was found to exhibit analgesic effects in trigeminal neuralgia and central neuropathic pain. The most common side effects are drowsiness, dizziness, and gastrointestinal distress.[116] Botulinum toxin inhibits acetylcholine release at the neuromuscular junction and may alleviate muscle spasticity. The use of botulinum toxin injections has produced inconsistent results in headaches and was not effective in myofascial trigger points, orofacial, or neck pain.[94,117,118] Side effects include pain and erythema at the injection site and unintended paralysis of adjacent muscles.

The synthetic peptide ziconotide blocks N-type voltage-sensitive Ca^{++} channels and thereby inhibits release of excitatory neurotransmitters from central terminals of primary afferent neurons in the spinal cord. It has been approved for intrathecal application but produces substantial side effects (dizziness, confusion, abnormal gait, memory impairment, nystagmus, hallucinations, vertigo, delirium, apnea, hypotension) and, thus, is suitable for only a small subset of patients with otherwise intractable pain.[119] Under the assumption of antiinflammatory activity, steroid injections are frequently used epidurally or perineurally, albeit without convincing evidence for effectiveness (see the later section, "Therapeutic Nerve Blocks").

Antiemetics are used to treat nausea, a frequent side effect of analgesics (particularly opioids) and a frequent complaint in cancer patients. Recommendations for the treatment of postoperative nausea and vomiting cannot readily be extrapolated to the chronic pain patient. For example, in cancer patients, etiologies other than opioids have to be considered, such as radiotherapy and chemotherapy, uremia, hypercalcemia, bowel obstruction, and increased intracranial pressure. In addition, pain itself, as well as anxiety, can cause nausea. Management guidelines for the treatment of nausea and vomiting are available and the selection of antiemetics should be mechanism-based.[67,120] The medullary chemoreceptor trigger zone, gastrointestinal stimulation or failure, vestibular and cortical mechanisms, as well as alterations of taste and smell, may contribute to nausea and vomiting, particularly in cancer patients. Most recommendations for the choice of antiemetic medication include gastrointestinal prokinetics (metoclopramide), phenothiazines (e.g., levomepromazine), dopamine receptor antagonists (e.g., haloperidol), serotonin antagonists (e.g., ondansetron), and antihistamines (e.g., cyclizine). In addition, the use of dexamethasone (unknown mechanism), anticholinergics (e.g., scopolamine), and neurokinin-1 receptor antagonists has been reported. Combinations of antiemetics with different modes of action can be used. Many of these drugs cause undesirable side effects by themselves (e.g., sedation, drowsiness, confusion, extrapyramidal symptoms).[67,120] The efficacy of cannabinoids and benzodiazepines is considered comparatively low and they are not recommended as first-line treatment.[120,121]

Laxatives are indicated when bowel movements are less than three per week, and are associated with difficulty or discomfort. Risk factors for constipation include opioid medication, older age, advanced cancer, hypokalemia, immobilization, as well as therapy with tricyclics, phenothiazines, anticonvulsants, diuretics, and iron supplements. Opioid-related constipation is mediated through intestinal and (partially) through central μ-receptors.[66] It is the most commonly occurring side effect of opioid medication in cancer patients and frequently does not exhibit tolerance. Ample fluid intake, fiber-rich nutrition, and mobilization are nonpharmacologic approaches to prophylaxis, but recommendations are mostly derived from anecdotal evidence.[122] Laxatives include bulk forming, osmotic, and hyperosmolar agents; substances for colonic lavage; prokinetic drugs; and opioid antagonists. Recommendations usually include lactulose, senna, or polyethylene glycol as a first choice.[67] However, lactulose should be avoided in patients with impaired fluid intake, such as the elderly and those with advanced cancer. If insufficient, the drugs of first choice may be combined with paraffin or anthraglycosides (bisacodyl). Rectal sorbitol or contrast medium are the choices for the next more intensified step. Prokinetic drugs, such as metoclopramide, are sometimes added for refractory constipation. A possible alternative in opioid-related constipation are opioid antagonists. To avoid central effects reducing analgesia or producing withdrawal, oral naloxone and the peripherally restricted antagonists methylnaltrexone and alvimopan were developed. Their use in clinical practice is limited by relatively low response rates, adverse effects, and high costs.[123]

DEVELOPMENT OF NOVEL ANALGESICS

Areas of intense research and examples emerging as potential drug targets include calcitonin-gene-related-peptide, Na^+ channels expressed in peripheral nociceptive neurons ($Na_v1.8$, $Na_v1.7$), voltage-gated Ca^{++} channels (e.g., $Ca_v2.2$), antibodies against nerve growth factor, the capsaicin receptor TRPV1, and the P2X receptors.[21] Increasing attention is paid to augmentation of endogenous opioid and cannabinoid mechanisms, to (biased) opioid receptor signaling, and to the activation of peripheral opioid receptors to avoid central side effects.[11,62-64,124,125] However, failures in clinical phases of analgesic drug development are common and have been attributed to inappropriate animal models or nociceptive tests, species differences, publication bias, lack of mechanistic understanding, shortcomings in experimental design, randomization, blinding, and statistical analysis.[21]

Interventional Methods used for Chronic Pain

The popularity of interventional methods has decreased over time. While early pain therapists (e.g., Leriche) were generally using "blocks" to treat pain, the biopsychosocial concept of chronic pain has led to a much more cautious and judicial use of such techniques (see earlier section, "Interdisciplinary Management of Chronic Pain"), particularly since most of these are not evidence-based. Block therapy alone is usually not curative, but it can facilitate participation in rehabilitation and therefore does have a role in the management of chronic pain. Regardless which procedure is considered, a consensus decision on its use has to be reached within the interdisciplinary team.

DIAGNOSTIC NERVE BLOCKS

Neural blockade is thought to be a useful tool to better understand the mechanisms underlying pain in an individual patient and to provide a prognosis for planned neuroablative procedures (particularly in cancer pain). Differential blockade aims to selectively block either single peripheral nerves to identify an anatomical pain source, or to selectively block only one type of nerve fiber (autonomic vs. somatic).[126] However, the clinical usefulness of these procedures could not be confirmed.[127,128] In particular, the validity of diagnostic nerve blocks is limited by the complexity of factors determining pain perception (see above section, "Biopsychosocial Concept of Pain" and "Interdisciplinary Management of Chronic Pain"). Furthermore, the assumption that local anesthetics can selectively produce conduction block of only one fiber type in a nerve is probably false.[126] Nevertheless, experienced and observant clinicians have found that such procedures may occasionally provide information that is helpful in guiding subsequent therapy, although systematic reviews had methodological limitations.[129,130]

THERAPEUTIC NERVE BLOCKS

Cancer Pain

Therapeutic nerve blocks are used only in a minority of patients with cancer-related pain. Here, interventional treatment represents the fourth step in the World Health Organization analgesic ladder.[131] About 90% to 95% of patients usually obtain adequate pain relief from pharmacologic management.[132] A comprehensive biopsychosocial approach to pain management—as in chronic noncancer pain—and carefully balancing risks against benefits in individual patients are prerequisites for successful use of interventional techniques.[133] Therapeutic nerve blocks extend the treatment range when conservative methods fail to achieve tolerable pain or side-effect levels (or both). For example, neuropathic, incidental, or breakthrough pain are sometimes poorly controlled by systemic analgesics and may be indications for invasive therapy. Well evaluated interventional techniques like celiac plexus block, hypogastric plexus block, and saddle blocks should not be withheld from cancer patients in a palliative symptom control context.[134]

Sites for neurolyses are intercostal nerves (e.g., in rib metastasis), the superior hypogastric ganglion, the ganglion impar, and the lumbar sympathetic ganglia (e.g., for pelvic tumors). In perineal pain due to local infiltration of rectum cancer, intrathecal neurolysis may be considered if bladder and sphincter function are not of concern.[134,135] An indication for thoracic intrathecal or epidural neurolysis might be advanced lung cancer.[136] As a neurolytic agent, alcohol may be preferred due to its perceived higher success rate and longer duration of pain relief (3-6 months) compared to phenol (2-3 months), although no studies directly comparing these two agents are available. The limited period of pain reduction and the limited possibility of repeat injections are reasons why neurolysis is mostly used in patients with short life expectancy.[137]

Non-Cancer-Associated Pain

Both the complexity of factors contributing to pain perception and perpetuation (see earlier in sections "Biopsychosocial Concept of Pain" and "Interdisciplinary Management of Chronic Pain") and the detrimental long-term effects of nerve destruction (neuropathic pain caused by spontaneous ectopic neuronal discharges, upregulation of neuronal ion channels, and excitatory amino acid receptors, see earlier in sections "Physiological Changes in Persistent Pain" and "Antiepileptic Drugs") caution against neuroablative procedures in the noncancer patient. Nonetheless, many practitioners advocate radiofrequency ablations or cryoneurolysis at facet joints, sacroiliac joints, and other destructive procedures. However, the IASP makes no conclusive recommendations due to the poor quality of available data.[138]

Nondestructive procedures include trigger point, epidural, perineural, and intraarticular injections of local anesthetics, or steroids (or both). Steroids are used under the assumption of antiinflammatory activity. For example, in chronic back or neck pain (the most common patient complaints), injections into facet (or zygapophyseal) joints or along the medial branch from the posterior ramus of the spinal nerve root are frequently performed, however, without convincing documented long-term results.[139,140] Similarly, injections into sacroiliac joints, trigger points, or occipital nerve blocks show no consistent long-lasting effects.[129,141,142] Epidural steroids are also used extensively for low back and neck pain,[143] but they provide questionable long-term pain relief in RCTs.[144] The same applies to lumbar transforaminal epidural steroid injections.[145] Thus, the described invasive procedures should be limited to acute pain states in patients without biopsychosocial risk factors for chronification of pain, and only as an element within a physical rehabilitation or multimodal treatment program.[146] Sympathetic nerve blocks with local anesthetics, often carried out as a series, such as in herpes zoster-associated pain and complex regional pain syndrome, are commonly used but evidence from RCTs is lacking.[147] Anecdotal reports have described sympathetic blocks for ischemic pain, such as in peripheral vascular or Raynaud disease.

CONTINUOUS CATHETER TECHNIQUES

Continuous drug delivery to the intrathecal or epidural space can be accomplished via programmable implanted pumps, implanted accessible reservoir systems, and tunneled exteriorized catheters. The principal benefit appears to be the reduction of systemic side effects. As with nerve blocks, the evidence of effectiveness of these approaches is stronger for cancer pain than for chronic nonmalignant pain.

Cancer Pain

Only a small minority of cancer patients require neuraxial (intrathecal, epidural) drug delivery due to intolerable side effects, but in patients refractory to systemic analgesics, such methods may be underused.[148,149] The preponderance of evidence supporting this mode of drug delivery is derived from nonrandomized, uncontrolled studies.[150,151] The advantage of the neuraxial technique is its ubiquitous availability in most anesthesia departments, but disadvantages are the chance of inhomogeneous distribution of the analgesics, possible systemic absorption, and limited duration of therapy due to local granuloma formation and technical failures.[151] Usually, morphine (1-15 mg, dependent on preceding systemic dosage) or hydromorphone are recommended as drugs of first choice for intrathecal catheter analgesia. For refractory pain, combinations with bupivacaine, clonidine, ziconotide, and other compounds have been used.[150]

Non-Cancer-Associated Pain

No RCTs are available, but a number of observational reports describe continuous catheter techniques for chronic noncancer pain.[151] Most of these studies used intrathecal morphine, and some hydromorphone, baclofen, or ziconotide in patients with chronic low back pain. On average, these patients exhibited increasing daily morphine doses over time, and a high incidence (up to 25%) of complications, such as catheter obstruction, catheter-tip granuloma formation, pruritus, urinary retention, and infection. Effectiveness of these techniques in relieving pain or improving function compared to placebo, natural history, or other treatments has not been shown[151] or is limited.[152]

STIMULATION TECHNIQUES

Stimulation techniques frequently used in pain management include acupuncture, spinal cord (or dorsal column) stimulation (SCS), and transcutaneous electrical nerve stimulation (TENS). Acupuncture has been popular among patients for a long time and lately also within the medical community. Systematic reviews of sham-controlled studies in migraine prophylaxis and arthritic pain showed that using traditional Chinese concepts of meridians and specified classic points are as effective as the selection of acupuncture points at random.[153,154] There is inconclusive evidence that acupuncture may be of benefit in osteoarthritis[154,155] and chronic low back pain.[156-158] SCS has gained new interest with the introduction of the high-frequency technique,[159] but its superiority still has to be demonstrated.[160] So far SCS has not been validated by adequately powered and blinded RCTs in chronic pain.[161,162] Unblinded studies suggest that selected patients with complex regional pain syndrome or back pain, especially with failed back surgery syndrome, might benefit from SCS, but controlled trials are needed.[138,163]

Perioperative Management of Patients with Chronic Pain

CHARACTERISTICS OF CHRONIC PAIN PATIENTS IN THE PERIOPERATIVE PERIOD

In chronic pain patients, central sensitization or reduced endogenous inhibition may result in increased and prolonged pain after surgery.[164] Altered opioid sensitivity due to long-term exposure to opioid medications also has to be considered.[165] In addition, chronic pain patients may exhibit higher preoperative expectation of pain, anxiety, depression, or hypervigilance.[166,167] It may be difficult to distinguish normal from maladaptive anxiety, but patients with cancer pain are more likely to be anxious than cancer patients without pain. In addition, the chronic pain patient, including the patient with cancer, is not as confident of recovery as other patients with chronic diseases.[168] Thus, difficult perioperative pain control and, possibly, an increased risk of chronic pain development after surgery have to be expected. However, chronic pain patients, with or without long-term opioid medication, opioid abuse or misuse, require and must receive adequate pain control.

The preanesthetic visit should therefore include questions regarding chronic pain and regular use of analgesics and adjuvant medication (also see Chapter 31). Although a number of characteristics including increased opioid

BOX 51.1 **Risk Factors in the Perioperative Management of the Chronic Pain Patient**

- Conventional perioperative analgesia regimens do not meet the needs of the chronic pain patient.
- Unrelieved postoperative pain due to undermedication may provoke withdrawal.
- Patients tend to underreport their medication.
- With uncontrolled anxiety or fear of pain, patients tend to overestimate the effect of painful stimuli.
- Epidural and intravenous (IV) opioid (including patient-controlled analgesia [PCA]) requirements can be 2-4 times higher in opioid-consuming than in opioid-naïve patients.
- Expect prolonged recovery and need for postoperative analgesia.
- Anxiety and insufficient coping result in poor compliance with analgesic strategies.
- Individual variations in response to opioids may necessitate selection of the optimal drug and dosing by sequential trials.
- Individual titration of doses to find the optimal balance between analgesia and adverse effects is required.
- Adjuvant medication may interfere with anesthesia and postoperative analgesia.

Adapted from Kopf A, Banzhaf A, Stein C. Perioperative management of the chronic pain patient. *Best Pract Res Clin Anaesthesiol*. 2005;19:59–76.[202]

demand, underreporting of pain, and noncompliance are known, only few specific recommendations are available, such as adequate increase of opioid dose for analgesia, continuation of preoperative analgesics to prevent withdrawal, and intensive education to strengthen the patient's coping potential. No differences between specific techniques for postoperative analgesia (e.g., systemic, patient-controlled, or regional analgesia) have been demonstrated so far. Furthermore, preoperative intensity of pain alone, independent of the use of analgesics, correlates positively with postoperative pain.[169] Chronic pain patients often suffer from prolonged inactivity or neurologic deficits (or both), which increase the risk for adverse events during the perioperative period. Some key issues are summarized in Box 51.1.

CHRONIC USE OF ANALGESICS AND ADJUVANT DRUGS

Chronic pain patients are often pretreated with opioids, COX inhibitors, antidepressants, or anticonvulsants (or combinations). Tolerance, drug interactions, and side effects may occur. In addition, inappropriate or excessive medication is commonly observed.[47,170] Chronic pain patients tend to underestimate and underreport their medication use.[171] Thus, undertreatment in the perioperative period may be unnoticed and may induce a neuroexcitatory withdrawal syndrome and associated cardiopulmonary strain.

Chronic opioid medication has been discussed thoroughly in the literature (see earlier in section "Opioids"). Together with aggressive marketing, this has gradually led to decreasing reservations among practitioners toward the use of these drugs. As a result, opioids are used more frequently in both cancer and noncancer pain patients and the majority of the latter are now prescribed opioid medication.[47,170] While this seems justified in cancer pain, opioids are usually not indicated in chronic noncancer pain (see earlier section "Opioids"). Nevertheless, anesthesia providers are increasingly confronted with patients receiving long-term opioid treatment. Such pretreatment can result in severalfold increased and prolonged requirement for systemic and epidural analgesics in the perioperative period compared to opioid-naïve patients.[73,172-174] Chronic pain patients with prior opioid consumption may also exhibit higher postoperative pain scores.[174] The increased postoperative analgesic demands may be due to lower pain thresholds or to a need for higher drug concentrations. In addition, opioid requirements can be influenced by gender, genetic predisposition, age, type of surgery, and preoperative pain levels.[74,169] On the other hand, opioid-related side effects (e.g., nausea and pruritus) may be less dominant. Physicians and nurses may overestimate tolerance, addiction, and sedation, but underestimate dependence. A paramount concern is the maintenance of adequate perioperative opioid dosing to prevent withdrawal (see Box 51.1).[173,174]

COX inhibitors are the most commonly used nonopioid analgesics. They produce serious side effects in the gastrointestinal tract, kidneys, cardiovascular and coagulation systems (see earlier section "Drugs Used for Chronic Pain"). Major concerns for the anesthesiologist are coagulation disturbances, renal impairment, and the increased risk for hematoma formation associated with spinal and epidural anesthesia.

Antiepileptic drugs can interfere with anesthesia in different ways. Sedation produced by anticonvulsant drugs may have additive effects with anesthetics, whereas drug-induced enzyme induction could alter responses to or contribute to the organ toxicity of anesthetics. Gabapentin has a favorable side effect profile, and its relative absence of drug interactions allow continuation and rapid titration in the perioperative period.[175] Phenytoin and carbamazepine accelerate recovery from nondepolarizing muscle relaxants, but the mechanism is unclear. Preoperative exclusion of toxic serum levels of phenytoin is recommended to reduce the risk of atrioventricular conduction block. States of disorientation, nystagmus, ataxia, and diplopia may be manifestations of excessive plasma concentrations. Carbamazepine may produce sedation, ataxia, nausea, and (rarely) bone marrow depression or hepatorenal dysfunction. Plasma sodium levels have to be monitored perioperatively to avoid hyponatremia. Oral valproic acid is commonly used for prophylaxis of migraine and intravenous valproic acid may be used to control episodic headaches.[176] It may inhibit activity of hepatic microsomal enzymes and interfere with platelet aggregation.[177] Antiepileptics should never be discontinued abruptly to avoid central nervous system hyperexcitability. Stable dosages need to be maintained throughout the perioperative period.

Antidepressants are frequently used for neuropathic pain and for associated depression. Adverse effects are numerous and include sedation, anticholinergic effects, and cardiovascular changes. Electrocardiographic changes, such as prolongation of PR-interval and widening of the QRS complex, can occur but previous suggestions of increased risk of perioperative cardiac dysrhythmias have not been substantiated in the absence of drug overdose.[178] Therefore, antidepressants need not be discontinued before anesthesia, but increased anesthetic requirements may be expected due to enzyme induction. Postoperatively, the likelihood of delirium and confusion may be increased as a result of additive anticholinergic effects. Selective serotonin reuptake inhibitors and atypical antidepressants like mirtazapin or venlafaxine are less likely to interfere with anesthesia.

Ketamine is a mixed opioid agonist/NMDA antagonist that can produce analgesia at subanesthetic doses in selected patients with neuropathic pain.[179,180] Very rarely, patients taking oral ketamine medication on a chronic basis will be encountered. In these cases, perioperative administration of ketamine should be discontinued because correct conversion from oral to intravenous ketamine is difficult.[181] Within analgesic dose ranges, the risk of a withdrawal syndrome is small.[180,182]

Benzodiazepines are not analgesic and are rarely used in chronic pain, with the exception of palliative care situations.[115,183] Nevertheless, since chronic pain is a predictor of increased benzodiazepine use, this should be explored in the preanesthesia visit.[184] Side effects relevant to anesthesia include sedation and skeletal muscle weakness. Due to their long half-life, delayed withdrawal should be anticipated and avoided by maintaining stable perioperative dosage. Neuroleptics are also inappropriate, but sometimes used in chronic pain.[185] In the perioperative period, patients treated with antipsychotic drugs can develop a neuroleptic malignant syndrome. Hyperthermia, hypertonicity of skeletal muscles, fluctuating levels of consciousness, and autonomic nervous system instability are typical symptoms.

DEPENDENCE, ADDICTION, AND PSEUDOADDICTION

Physical dependence is defined as a state of adaptation that is manifested by a drug class-specific withdrawal syndrome that can be elicited by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, or administration of an antagonist.[186] Dependence is not synonymous with tolerance (see earlier section “Opioids”). All opioids, benzodiazepines, and anticonvulsants produce clinically relevant physical dependence when administered for a prolonged period of time, but sometimes physical dependence can develop within hours of agonist exposure.[71] Thus, all patients with continuous preoperative opioid intake should be considered at risk for withdrawal syndrome if adequate substitution of opioids in the perioperative period is withheld. Opioid and benzodiazepine withdrawal syndromes, especially tachycardia and hypertension, may be detrimental for the high-risk cardiac patient. Rapid withdrawal from anticonvulsant drugs may trigger seizures, anxiety, and depression.

Addiction is a behavioral syndrome characterized by evidence of psychological dependence (craving), uncontrolled/compulsive drug use despite harmful side effects, and other drug-related aberrant behavior (e.g., altering prescriptions, manipulating healthcare providers, drug hoarding or sales, unsanctioned dose escalation).[186,187] The prevalence of opioid addiction is up to 34% in patients with chronic nonmalignant pain and about 8% in patients with cancer pain.[187,188] Special considerations in the management of the drug-addicted patient are discussed elsewhere.[173,174,189]

MANAGEMENT AND PRACTICAL RECOMMENDATIONS

Perioperative management has to address the risk of opioid withdrawal, the altered pain sensitivity, and the psychological alterations typical in the chronic pain patient population. Most of the following recommendations have to be considered as “expert views” only.[174,190,191]

Preoperative Evaluation (also see Chapter 31)

Preanesthesia evaluation is necessary to educate patients, to organize resources for preoperative improvement of the patient’s physical function, to choose optimal anesthetic techniques, and to formulate plans for postoperative recovery, including perioperative pain management.[173] Misconceptions about the surgical procedure, the role of the anesthesiologist in perioperative care, and postoperative pain treatment are common among patients.[192] A thorough history must be obtained to identify all preoperative medications, including opioids, other analgesics and adjuvants, as well as signs of psychiatric comorbidity and aberrant drug-related behavior. Patients with spinal cord stimulators should be instructed to turn off the device. Screening tools and thorough education of the patient are recommended.[167,193] Consultation of a pain specialist should always be considered. Pertinent issues and practical recommendations are summarized in Boxes 51.1 and 51.2.

Perioperative Management

To avoid opioid withdrawal, the preoperative systemic dosage should be continued throughout the perioperative period and mixed agonist/antagonists (buprenorphine, nalbuphine) must be avoided. If a neuraxial catheter with opioid medication is used, the flow and concentration of the opioid should be continued throughout the perioperative period as background analgesia.[194] For minor and medium surgery, oral slow-release opioid medication may be continued at its regular intervals. For major surgery with postoperative restriction of enteral intake, oral opioids should be discontinued and replaced by equivalent doses of intravenous opioids, which have to be continued for the entire perioperative period. This applies to general as well as regional anesthesia. The anesthesia technique should be selected on an individual basis considering the patient’s expectations since no data are available favoring general, regional, or combined anesthesia for this patient population.[191] The frequency and extent of monitoring techniques should be adapted to the risk of patient instability.

Individually adapted regimens are usually superior to “conventional” analgesia, regardless of the specific analgesia technique used.[195] In minor and medium surgery, an opioid/NSAID combination should always be considered to enhance opioid effects. Since pregabalin and gabapentin can reduce postoperative pain and opioid consumption[196] and have anxiolytic effects,[197] the chronic pain patient with anxiety might benefit. A dose range of 150 mg BID until the second or third postoperative day has been recommended.[190] Ketamine may also be applied as an adjunctive therapy,[180] but there are no data to encourage its routine use for the chronic pain patient in the perioperative period. Support from a multimodal pain treatment facility or the acute pain service should be requested. Apart from the

BOX 51.2 **Preoperative Considerations and Recommendations in Patients With Chronic Pain**

- Take thorough history to identify all analgesic and adjuvant medications, risk factors, and comorbidity.
- Educate the patient about the perioperative procedures, the potential for aggravated pain, and increased opioid requirements.
- Communicate plans between the designated anesthesiologist in the operating room, the postanesthesia care unit, and the surgical and nursing personnel on the ward.
- Differentiate between addiction, pseudoaddiction, and physical dependence in patients on long-term opioid medication.
- Expect physical dependence in patients on long-term opioid medication.
- Continue previous long-acting opioid analgesics for short procedures.
- For major surgery calculate and order background infusion of an equianalgesic opioid dose for patients with NPO for >8 h to be started in the OR.
- Order regular opioid medication on the morning of surgery.
- Maintain anticonvulsant drugs and benzodiazepines at preoperative doses.
- Discontinue all other adjuvants if NPO status remains >24 h.
- Identify untreated depressive disorder with screening questions for disturbed sleep, lowered mood, reduced concentration, self-confidence, and motivation.
- Identify untreated anxiety disorder with screening questions for restlessness, irritability, difficulties to control anxiousness, and worrying.
- Consider referral to pain specialist for evaluation.
- Choose regional or general anesthesia based on individual considerations.

OR, Operating Room.

Adapted from Farrell C, McConaghy P. Perioperative management of patients taking treatment for chronic pain. *BMJ.* 2012;345:e4148; and Kopf A, Banzhaf A, Stein C. Perioperative management of the chronic pain patient. *Best Pract Res Clin Anaesthesiol.* 2005;19:59–76.[191,202]

choice of analgesia technique and adequate opioid medication, optimization of organizational structures is a key factor for improving perioperative analgesia.[198] If addiction is suspected the patient should be re-evaluated for weaning or rehabilitation only after recovery from surgery and postoperative pain.[199] Specific risk factors in chronic pain patients are summarized in Box 51.1.

Postoperative Regional Anesthesia

Although there is no strong evidence indicating superiority of particular anesthetic techniques for postoperative analgesia in chronic pain patients, individual considerations may favor regional anesthesia, particularly because these patients are prone to intensified postoperative pain experiences. Chronically opioid-consuming patients need their daily systemic dosage by the intravenous or oral route to prevent withdrawal.[173] In addition, postoperative analgesia with an epidural or plexus catheter may be accomplished with a combination of local anesthetics and opioids, similar to patients without chronic pain (see Chapters 45 and 46). However, higher doses of epidural opioids are recommended since cross-tolerance between orally and epidurally administered opioids has been described. Epidural lipophilic opioids (fentanyl, sufentanil) may provide better postoperative pain relief than epidural morphine in chronically opioid-consuming patients, which has been attributed to the need of a lower receptor occupancy or incomplete cross-tolerance between morphine and sufentanil.[200]

Postoperative Intravenous Opioids

The total required opioid dose consists of the daily dose taken before and the dose made necessary by surgical stimulation. A continuous perioperative intravenous opioid infusion equivalent to the regular daily dosage is recommended if the oral route is unavailable.[173,195] Additional bolus doses of opioid or nonopioid analgesics (or both) have to be titrated to individual needs to achieve adequate pain control in the postanesthesia care unit. Depending on the local circumstances, this may be patient-, nurse- or physician-controlled. The bolus size should be equal to the hourly dose of the background infusion. Once the patient demands less than four extra bolus doses per day, the background infusion may be reduced in daily steps of about 20% to 30%. For calculation of opioid dose equivalents, the relative potency, half-life, bioavailability, and route of administration have to be considered.[201] As soon as possible, oral medication should be resumed. Intravenous doses during the first 24 to 48 hours after surgery should be converted to oral dose equivalents. Half of the total dosage may be delivered as long-acting and half as short-acting breakthrough medication for on-demand use.[173]

Perioperative Transdermal Opioids

Transdermal fentanyl patches are relatively reliable in administering controlled amounts of the drug to the circulation over long periods. However, during surgery the amount of drug delivered to the patient may significantly shift. Changes in intravascular volume, body temperature, and volatile anesthetics alter skin permeability and perfusion resulting in relatively large fluctuations in transdermal fentanyl passage. In addition, forced-air warming blankets and heat packs applied onto the patch itself can lead to several-fold increases in fentanyl permeation through the skin.[73] Thus, in major surgery, removal of transdermal systems is advisable to avoid unforeseen decreases and increases of systemic opioid uptake. The transdermal opioid dose should be converted to intravenous morphine to be administered as a continuous background infusion.[201] Pertinent issues and practical recommendations are summarized in Box 51.3.

BOX 51.3 Intra- and Postoperative Management Issues and Practical Recommendations

- Start background opioid infusion immediately when patient arrives in the OR.
- Remove opioid patch when major surgery is planned; in minor surgery patch may be continued without background infusion.
- Every chronic pain patient has to be seen postoperatively tid to evaluate pain at rest, pain with exercise (e.g., coughing), nausea, sedation, mobilization, and sleep quality.
- Monitor closely for signs of respiratory depression and of withdrawal (e.g., unexplained tachycardia, restlessness, sweating, confusion, hypertension).
- Integrate the patient in the acute pain service protocol if available.
- Titrate short-acting opioid for acute pain with 2-4 times the usual starting dose needed for an opioid-naïve patient.
- Add COX inhibitors, anticonvulsants, other adjuvants as needed.
- Evaluate demand-delivery-ratio of PCA frequently, adapt demand-dose in relation to background infusion (demand-dose equals hourly dose of background infusion).
- Increase background infusion in PCA in relation to the cumulative daily opioid demand dose (add 50%-75% of the daily demand-dose to background infusion).
- Change technique of postoperative analgesia if inadequate use persists in spite of repeated patient education.
- In case of insufficient epidural analgesia with morphine, use epidural fentanyl or sufentanil.
- In case of IV opioid dose escalation consider spinal/epidural opioid application or switch IV agonist.
- Reduce daily opioid doses after the second postoperative day stepwise to the preexisting dose.
- Switch back to oral or transdermal medication as early as possible; use 50%-75% of last daily IV opioid dose as slow release oral or transdermal delivery plus the rest as demand dose.
- When switching back to transdermal route consider 12-16 h delayed effects and supply patient for this period with sufficient on-demand analgesia.
- Do not attempt to solve a chronic pain problem in the immediate postoperative period.
- Use non-pharmacological techniques (distraction, relaxation) where appropriate and offer counselling in the pain unit after postoperative recovery.

Palliative Medicine

ANN CAI SHAH, ANNE L. DONOVAN, and SARAH GEBAUER

KEY POINTS

- Palliative care is an interprofessional approach to symptom management and decision making for patients with a wide range of serious illnesses and is not limited to patients who are imminently expected to die.
- Palliative care teams reduce costs and decrease the burden of symptoms for patients with serious illnesses.
- Physicians receive limited training in discussing difficult topics and tend to focus on details and use medical jargon in conversations with seriously ill patients.
- Patients and families want physicians to be truthful and empathetic and to participate in shared decision making.
- While patients and families desire a prognosis, they understand and accept that physicians have difficulty prognosticating the future for an individual patient.
- Opioids administered in small doses are effective in treating dyspnea and do not hasten death in patients receiving palliative care.
- The presence of treatment limitations should prompt a thorough discussion of the perioperative plan between the patient and the surgical team.

What Is Palliative Medicine?

DEFINITION

The World Health Organization (WHO) defines palliative care as "an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual."[1] Importantly, palliative care does not necessarily need to be limited to the end of life. The Center to Advance Palliative Care states, "unlike hospice care, palliative care can be provided at the same time as curative treatments; it is appropriate at any age and at any stage of a serious illness." Illness has many facets; symptom management, family support, and aid in decision making are common areas of focus for palliative care teams (Fig. 52.1).[2] Symptom management encompasses physical symptoms (i.e., pain, constipation, nausea and vomiting, and delirium) as well as emotional symptoms (i.e., depression, anxiety, and distress). Palliative *care* refers to the work of an interprofessional team, whereas palliative *medicine* refers to the medical subspecialty focused on providing symptom relief and decision-making support for patients with serious illnesses.

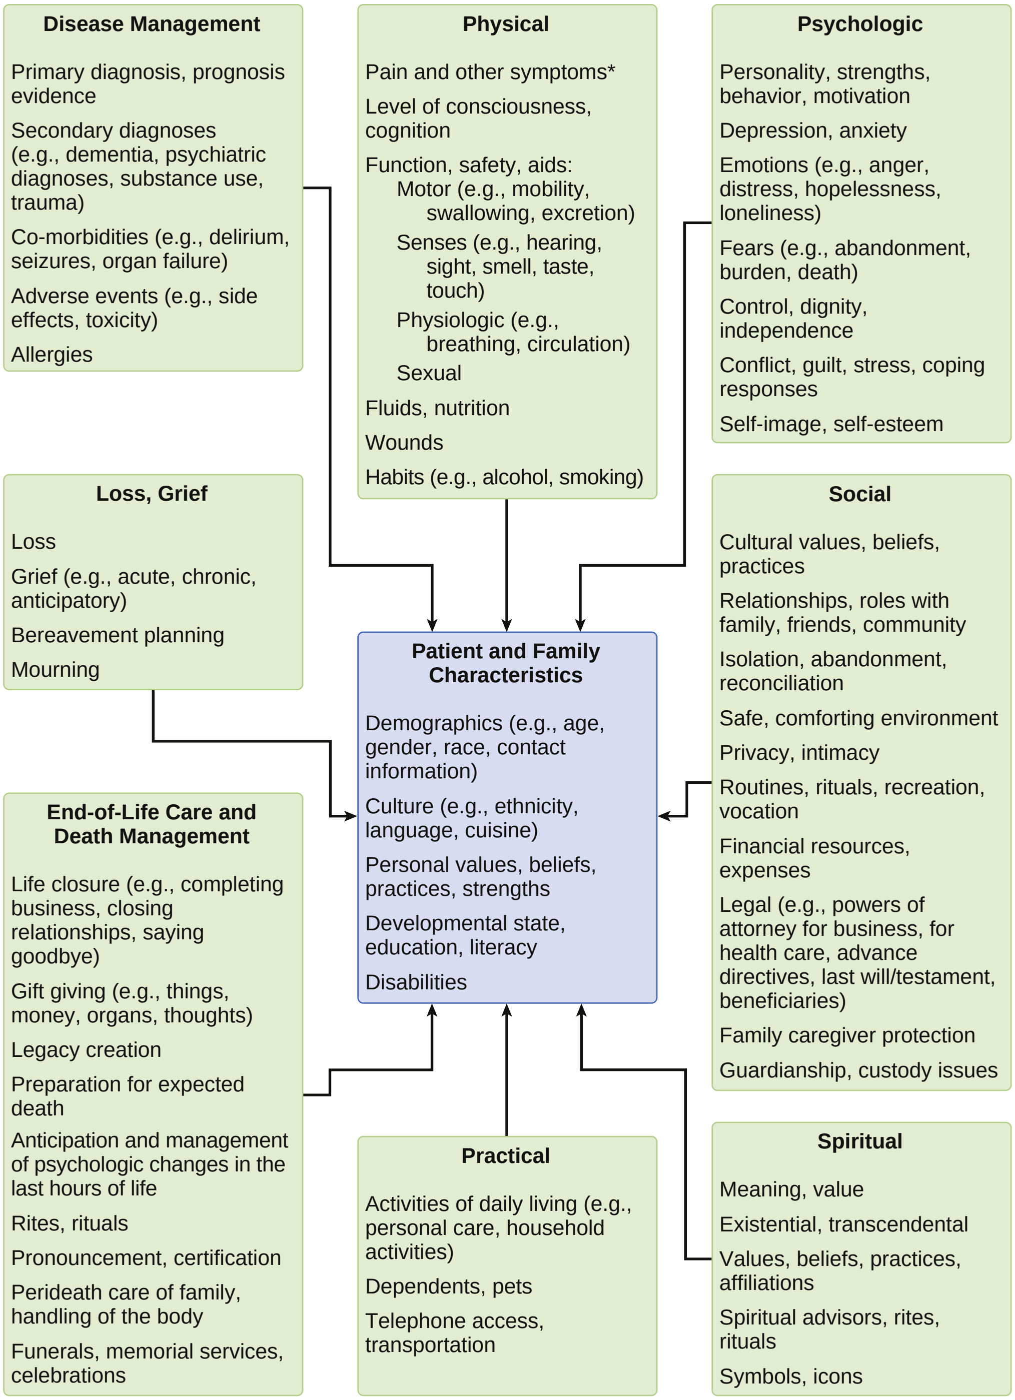
PRIMARY VERSUS SPECIALIST PALLIATIVE MEDICINE

There is a distinction made among the levels of palliative care: primary versus specialist. This distinction facilitates the differentiation among the skills expected from all physicians, including anesthesiologists, and from those more suitable to a specialist service. Examples of primary palliative medicine include basic pain and symptom management, as well as discussions about prognosis, goals of treatment, and resuscitation status.[3] Specialty palliative medicine includes the management of refractory or complex symptoms, as well as the facilitation of conflict resolution among families, staff members, and treatment teams related to the goals of care (Fig 52.2).[4]

HISTORY OF PALLIATIVE MEDICINE

The word *palliative* comes from the Latin word *to clothe* and refers to the "covering up" of symptoms such as pain. Modern palliative medicine grew out of the hospice movement started by Dr. Cicely Saunders in the late 1960s,[5] and introduced in the United States in the 1970s. Since that time, the field has broadened from a focus on patients at the end of life to include patients with serious illnesses. There is also growing recognition that many hospice principles, such as the relief from suffering, apply to all patients regardless of prognosis (Fig. 52.3).[6] To meet this growing need, several academic medical centers have organized inpatient palliative care teams over the past decades.[7]

Currently, 90% of hospitals with more than 300 beds and 67% of hospitals with 50 or more beds have palliative care teams.[8] Hospice and palliative medicine became a recognized subspecialty in 2006, with the first board examinations offered in 2008. Physicians from 10 medical specialties, including anesthesiology, are eligible to complete a fellowship and take the board examination.[9] Between 2008-2017, 125 anesthesiologists were also certified in hospice and palliative medicine.[10] There are now over 7600 hospice and palliative medicine physicians in the United States, and 1% to 2% of graduating



Disease Management
Primary diagnosis, prognosis evidence
Secondary diagnoses (e.g., dementia, psychiatric diagnoses, substance use, trauma)
Co-morbidities (e.g., delirium, seizures, organ failure)
Adverse events (e.g., side effects, toxicity)
Allergies

hospice and palliative care fellows each year are from anesthesiology.[10a,b]

WHY IS PALLIATIVE MEDICINE NEEDED?

The combination of an aging population and medical advancement has contributed to an increase in the number of patients with chronic illnesses. In the United States, Medicare expenditures currently exceed $600 billion, with 42% of Medicare expenses going to 5% of patients.[11] Many of these patients have multiple comorbidities, repeated or prolonged hospitalizations, or a life expectancy of less than 1 year, which make many of them appropriate for hospice or palliative care services.[12]

Patients with serious illnesses have a significant symptom burden, most often involving pain, dyspnea, anxiety, and

depression, and their family members report similar concerns.[13] Pain control during a life-limiting illness is often a major concern for patients and their families, and unfortunately, several surveys have found that they are often dissatisfied with the quality of pain control.[13,14] Patients and families also describe poor communication with health professionals, particularly in the setting of conversations regarding prognosis.[15] Palliative care, with its emphasis on symptom management and goal setting, attempts to address these concerns.

WHY IS PALLIATIVE MEDICINE IMPORTANT TO ANESTHESIOLOGISTS?

As patients who are older and more seriously ill undergo surgery,[16] anesthesiologists should develop an understanding of the concepts of palliative medicine. Anesthesiologists have specific skills in symptom management that may benefit the patient, and they have a unique perspective on the surgical process that can provide insight to palliative medicine and surgery teams.[17] As more patients and families interact with palliative care teams, anesthesiologists should be able to discuss related concerns and to develop an anesthetic plan that includes palliative concepts, including goals of care discussions and symptom management. Additionally, many pain and critical care anesthesiologists develop this specific expertise through their frequent management of seriously ill patients.

GLOBAL PALLIATIVE CARE

Approximately one half of the countries in the world have at least one hospice or palliative care service, although most exist in larger and more developed countries. Methods and locations of palliative care delivery are widely variable throughout the world, depending on the country's infrastructure. The variation in availability is vast, from 1 physician for every 1000 inhabitants in the tiny country of Niue near New Zealand to 1 per 8.5 million inhabitants in China and 1 per 90 million in Pakistan.[18] The access to appropriate medications is often restricted and variable as well. An estimated 80% of people with pain worldwide are unable to access opioids, due to concerns about addiction or restrictive

national opioid policies.[19] The WHO has implemented a "Public Health Strategy for Palliative Care" that incorporates aspects of policy, drug availability, and education to customize and integrate palliative care throughout the globe.[20]

PALLIATIVE CARE TEAM

Guidelines suggest that professionals with skills to meet the patient's and family's physical, psychological, social, and spiritual needs participate in the creation of a specialized care plan. Ideally, teams are interprofessional and include a nurse, physician, social worker, and chaplain, as well as other professionals, depending on the need.[21] Many professional disciplines have developed specialized certification or training in palliative care (Box 52.1).

BOX 52.1 Members and Roles in a Palliative Care Team

Physician	Diagnoses, treats, and manages a wide variety of medical issues for patients Provides expert symptom management and consultation Provides expert skills and consultation in communication with patients who are seriously ill, their families, and other providers
Nurse	Participates in the diagnosis, treatment, and management of acute and chronic serious illnesses within his or her scope of practice Assesses the patient's psychosocial and spiritual needs in the setting of a serious illness Participates in symptom management within his or her scope of practice Uses unique skillsets to communicate with the patient, family, healthcare team, and community
Social worker	Addresses the psychosocial needs of patients and their families affected by serious illness Participates in meetings with the medical team, patients, and families Assists in complex discharge needs and communicates with community resources
Spiritual advocate	Assists patients and families in identifying and addressing spiritual distress related to serious illness Provides or facilitates appropriate spiritual or religious rituals Provides liaison services to community spiritual resources
Additional professionals who provide expertise to the palliative care team	Anesthesia pain experts Pharmacists Rehabilitation therapists Psychiatrists

Where Is Palliative Care Delivered?

In the United States, palliative care is often delivered by a consult service in hospitals or in an inpatient unit.[6] Approximately two thirds of U.S. hospitals and 85% of middle-to-large hospitals have palliative teams, but again, access varies, depending on the geography and type of hospital.[22] The south-central states have the least access to palliative care with less than one third of hospitals in Arkansas, Mississippi, and Alabama reporting a palliative care team. By contrast, the northeast has the best access to palliative care. All hospitals in New Hampshire and Vermont report palliative care programs, as do 89% in Rhode Island and 88% in Massachusetts. While cancer patients who are admitted to the hospital may have high mortality and often have symptoms that are difficult to manage, only 20% to 26% of U.S. cancer centers offer dedicated palliative care inpatient beds.[6,23] Palliative care clinics are increasingly available, but home palliative care for patients who are not eligible for hospice is rare in the United States due to lack of reimbursement.[6]

INPATIENT PALLIATIVE CARE TEAMS

Outcomes With Palliative Care Teams

Inpatient palliative care teams reduce hospital costs and resource utilization. A retrospective study of six hospitals with well-established palliative care teams showed a decrease of $1700 per admission for patients discharged alive and $5000 for patients who died.[23a] A study of Medicaid beneficiaries showed hospital costs decreased by an average of $6900 during an admission once palliative care teams became involved with reduced intensive care unit (ICU) length of stay[24] and fewer ICU deaths.[25] A cohort study of over 41,000 inpatients who received an inpatient palliative care consultation for goals of care showed significantly reduced future acute care costs, healthcare utilization, and 30-day readmissions when compared with a propensity-matched cohort that did not receive a palliative care consultation.[25a] Studies examining inpatients with advanced cancer have demonstrated greater cost savings when a palliative care consultation is requested earlier in the hospital stay,[25b] and in patients with more comorbidities.[25b] Earlier palliative care consultations also help to facilitate building consensus around goals of care and use of invasive means to support life.[26] Inpatient palliative care teams improve patient-centered outcomes including quality of life,[27] patient and caregiver satisfaction,[27] and, to a variable degree, symptoms.[28,29] Importantly, palliative care consultation does not increase in-hospital mortality,[24,30] and even has been shown to lead to fewer days in the hospital and fewer inpatient deaths.[30a] This fact may be important for families and patients who incorrectly view palliative care as hastening death.

When to Consult Palliative Care Teams

Basic palliative care knowledge and skills are necessary for all clinicians; however, certain situations call for the expertise of a palliative care specialist. A variety of indicators have been developed to help physicians decide when a specialty palliative care assessment should be performed. Patients' palliative care needs should be assessed first by the treating physician, then a consultation with a palliative medicine specialist should follow when warranted. The presence of a potentially life-limiting (e.g., multiorgan failure, major trauma, sepsis) or life-threatening condition (e.g., metastatic cancer, cirrhosis, chronic renal failure) serves as the foundation for specialty palliative care involvement.[31] The palliative care candidate should also fit at least one additional criterion, such as frequent hospital admissions for the same condition, functional decline, or an ICU stay of 7 days or longer. More specific consultation criteria should take into account the local hospital system, resources, and patient population. Each hospital should develop a procedure for identifying patients who would benefit from palliative care consultation,[31] which often includes assistance with symptoms that are difficult to control, complex decision making, and provider or family support.

Palliative Care in the Surgical Intensive Care Unit

The three main models of palliative care integration in the ICU are the consultative model, the integrative model, or a hybrid model.[32] In the consultative model, a specialist palliative care team makes recommendations to the primary physician regarding the care of the patient. In the integrative model, the surgeon or intensivist identifies and addresses issues related to palliative care without specialist input. Hybrid models that combine the two approaches above also exist. The most effective model is not clear at this point and is often determined by hospital resources and culture.

Many quality improvement efforts have been proposed to improve palliative care integration into ICUs.[32a] One such effort involved screening of critically ill patients followed by direct communication between palliative care providers and intensivists for patients meeting prespecified criteria. This led to increased palliative care consultations in the medical intensive care unit (MICU) by 113% and in the surgical intensive care unit (SICU) by 51% over a 1-year timeframe.[32b] Although initial palliative care efforts and research have focused on MICUs, increased attention is being focused on providing palliative care to appropriate patients in the SICU.[32]

Trigger Criteria in the Surgical Intensive Care Unit

Surgical patients who die in the ICU often follow one of two courses. The first is characterized by a prolonged hospital stay with multiple transitions between acute care and ICU settings and intervening periods of prognostic uncertainty, while the second often occurs in trauma patients or other more acutely ill surgical patients with a rapidly declining course.[32] One study of patients in a trauma ICU showed that early assessment of patient and family preferences and early interdisciplinary meetings led to unchanged mortality, do not resuscitate (DNR) orders, and withdrawal of life support; however, the DNR and withdrawal orders were completed earlier in the hospital stay, and the ICU length of stay decreased in patients who ultimately died.[26] Focus on identification of appropriate palliative care consultations early in the hospital course is increasingly important, particularly in the former group.

Use of trigger criteria, in which the presence of one or more predefined patient risk factors results in automatic palliative care consultations, has shown encouraging results.[24] In a broad population of critically ill patients, the use of specific screening criteria to proactively initiate a palliative care referral decreases ICU resources utilization without affecting mortality.[32c] Employment of these screening or trigger criteria encourages proactive and systematic patient screening, thereby eliminating the biases of individual providers in identifying patients that would benefit from palliative care team involvement.[32] For example, one study examined the effect of implementing a structured palliative care intervention followed by an interdisciplinary family meeting within 72 hours of admission for all liver transplant service patients admitted to the SICU.[32d] After the intervention, increases were seen in goals of care discussions on rounds, documented patient code status, and withdrawal of life support, whereas decreases were seen in time to placing a DNR order and ICU length of stay. There was no difference in mortality, and family members indicated that they had more time with their loved one.[32d]

The most effective trigger criteria for palliative care consultations in SICUs have not been defined.[32] Creation of universal criteria is complicated by variation among surgical patient populations, along with many other factors. Many proposals include some combination of these considerations: lengths of stay in the ICU, the lack of improvement during the ICU stay, the patient's age, and the patient's illness.[32] One study performed in the SICU used 10 triggers based on expert opinion. These triggers included multiorgan system failure, SICU stay longer than 1 month, more than three SICU admissions during one hospitalization, and death expected during a current SICU admission.[33] This study showed no increase in palliative care consultation, but only 6% of the patients in this study met the trigger criteria, and although the attending physician was notified when a patient met the criteria, palliative care consultation was still left to the judgment of the attending physician.[33] A more inclusive screening process or a mandated palliative care referral, as observed in some of the successful medical ICU studies,[24] may have altered these results. Current recommendations suggest that referral criteria should be informed by available data but individualized for each hospital, or even each ICU, using input from stakeholders including palliative care providers, intensivists, hospital leadership, and nonphysician ICU care providers.[32c]

OUTPATIENT PALLIATIVE CARE

Outpatient palliative care clinics exist to follow patients after discharge or to provide outpatient symptom management and psychosocial support.[34] The providers, availability, and focus vary widely.[34] A landmark study by Temel in 2010 randomized 151 patients with metastatic non-small-cell lung cancer to early outpatient palliative care plus the standard oncologic care or standard oncologic care alone. Patients in the palliative care group had higher quality of life scores, as well as fewer symptoms of depression.[35] Perhaps most surprisingly to some, the patients in the palliative care group lived a median of 2.7 months longer than those in the standard care group, despite receiving less aggressive care.[35] These results and others have led to a recommendation by the American College of Chest Physicians that palliative care be introduced early in the course of disease for patients with stage IV lung cancer or a high symptom burden.[36] A systematic review of patients with a variety of terminal illnesses showed that outpatient palliative care improved depression and quality of life, reduced aggressive care at the end of life, increased advanced directives, reduced hospital length of stay and hospitalizations, and improved family and caregiver satisfaction. A Cochrane review found that while the effect sizes were small, early palliative care interventions may improve quality of life and symptom intensity in patients with advanced cancer. In 2017, because of multiple new randomized controlled studies in other cancers, the American Society of Clinical Oncology Clinical Practice Guideline expanded their recommendations for early palliative care consultation to cover all advanced cancer, not just advanced lung cancer.

Differences Between Hospice Care and Palliative Care

In contrast to palliative care, the definition of hospice care as it applies to the type of patient, the involvement of the medical team, and the setting, varies between countries.[39] In some countries, the terms hospice care and palliative care are interchangeably used, but in the United States, hospice care refers to a benefit provided by the governmental healthcare system. Patients are eligible to enroll in hospice care when their life expectancy is less than 6 months, and typically after life-prolonging treatments, such as chemotherapy, are stopped. Despite the logistic differences, the philosophy of hospice care generally focuses on reducing suffering, enhancing the quality of life, and supporting the patient and family (Fig. 52.4).

Continuous Features

- Multidisciplinary team
- Symptom management: pain, dyspnea, psychosocial
- Focus on quality-oriented care
- Family support
- Attempts to minimize suffering

Early Palliative Care	Hospice Care
• Appropriate at any stage of serious illness • Often provided in hospitals or outpatient clinics • Can be used in conjunction with "aggressive" care • Free-for-service model	• Prognosis <6 months (can be renewed every 60 days) • Focus on home-based care • Patient usually agrees to focus on comfort rather than life-prolonging treatments • Through Medicare, billed on a per-diem rate

Medicare Hospice Benefits
Personnel:
• Physician of patient's choice
• Nurse
• Aide
• Social worker
• Spiritual counselor
• Volunteers
Goods and services:
• Nursing support available on-call 24/7
• Access to short-term inpatient and continuous in-home care
• Bereavement support for 1 year after the patient's death
• Medical equipment (e.g., bed, walker)
• Medical supplies (e.g., bandages, catheters)
Not covered:
• Custodial care
• Some treatments at the discretion of the hospice unit
• Medications, hospitalizations, and treatments not related to the hospice diagnosis

Fig. 52.5 **Aspects of the Medicare hospice benefits.**

HOSPICE CARE IN THE UNITED STATES

In the United States, hospice is a per-diem capitated payment system for a defined set of services for patients with a life expectancy of 6 months or less, as agreed on by two physicians.[40] Medicare pays for approximately 80% of hospice care in the United States, and many private insurers have established similar guidelines. These services include visits to a patient's residence by a nurse (the main provider of clinical care[41]), aide, social worker, and chaplain.[40] Family members are also eligible to receive a year of bereavement counseling.[40] Continuous care and short-term hospital admission are available for patients with uncontrolled symptoms. A core set of requirements for the hospice benefit exists (Fig. 52.5). However, beyond these requirements, each hospice unit can decide which treatments to cover, and this coverage can vary widely. For example, some hospice organizations may cover palliative radiation treatments, whereas others may not. Patients who outlive their 6-month prognoses may have their benefits extended in 60-day increments after a face-to-face visit with a physician, recertifying that the patient continues to meet hospice criteria.

Who Is Eligible for Hospice Care?

To qualify for hospice, an attending physician and a hospice medical director must certify that the patient's prognosis is less than 6 months if the disease runs its normal course.[40] Medicare has created guidelines that describe eligibility criteria for hospice services, although the opportunity for interpretation does exist. For example, the criteria for a patient with chronic lung disease include disabling dyspnea at rest, poor response to bronchodilators, hypoxemia at rest, and repeated hospitalizations for emergency department visits.[41] As a result of the subjectivity of some of the guidelines, some hospices may accept patients that other hospices deem ineligible. Patients are not required to have a DNR order to be enrolled in hospice.

Recipients of Hospice Care

Although patients with cancer were previously the primary recipients of hospice care, the proportion of patients receiving hospice care with noncancerous diagnoses such as dementia, chronic obstructive pulmonary disease (COPD), and congestive heart failure (CHF) has increased from 16% in 1990 to 69% in 2010.[42] This increase is particularly problematic, considering the lack of good prognostic criteria for a 6-month life expectancy in some disorders, which can complicate hospice referral timing.[43] During this same period, the percentage of patients with Medicare who died while receiving hospice care increased from 5.5% to 44%,[42] yet the length of enrollment in hospice remains abbreviated. The median length of stay in hospice was 18 days in 2010,[42] and approximately one third of all hospice patients lived for less than 1 week after admission to hospice care.[41] Based on utilization review, 14.3% of Medicare patients with cancer did not enroll until the last 3 days of life.[43a] This trend toward late admission suggests that many patients are referred to hospice well after they are eligible.

Outcomes of Hospice Care

Hospice care decreases patient symptom burden[44] and increases caregiver satisfaction, with 98% of family members recommending hospice care to others.[41] A survey of over 1500 bereaved family members showed that 70% of respondents whose family member received hospice services considered the care "excellent" with less than 50% of those with decedents receiving home health services considering the care "excellent."[45] Studies related to cost effectiveness vary in their conclusions. Yet, a few studies suggest that the length of hospice use is correlated with cost savings.[44,46] A 2007 study by Taylor suggested cost savings with a hospice stay of 53 to 107 days,[46] whereas a 2013 study by Kelley showed cost savings with shorter hospice stays as well.[44] In a study looking at projected savings for beneficiaries with poor-prognosis cancers, increasing hospice utilization from 60% to 80% and increasing duration from 2 to 6 weeks could save $1.79 billion annually.[46a]

PALLIATIVE CARE AND ANESTHESIOLOGISTS

Anesthesiologists, as well as subspecialists in pain management and critical care medicine, are likely to interact with patients who are receiving palliative care services. Awareness of the goals of care in the palliative and hospice setting and what services are provided will help the anesthesiologist develop an appropriate plan based on the individual patient's goals. Critical care anesthesiologists are often called upon to aid in the determination of hospice eligibility and to help families discuss care plans. Pain medicine physicians may provide medication management and interventional procedures alongside palliative care physicians or as part of hospice benefit.

Surgery in Seriously Ill Patients

Palliative surgery has been defined as "the deliberate use of a procedure in a patient with an incurable disease with the intention of relieving symptoms, minimizing patient distress, and improving the quality of life."[51] A 2004 study of over 1000 patients with advanced cancer undergoing palliative surgery showed a 30-day morbidity of 29% and mortality of 11%, with 80% of patients experiencing improved symptoms at 30 days. A similar study by the same author in 2011 showed a significant improvement from their earlier study. Of 227 patients, there was a morbidity of 20% and mortality of 4%, with 90% experiencing symptom resolution.[51,53] The study authors attribute some of this change to better patient selection through shared decision making with patients and families.[51]

Communicating Surgery Risk in Seriously Ill Patients

Decision making concerning surgery near the end of life is complex; while some surgeries may increase quality of life or allow a patient to achieve a specific goal, others may result in excessive pain, functional decline, prolonged ICU or hospital stay, or increased use of resources without a clear benefit. A need exists to improve the quality of preoperative communication, to support decision making by surgeons and patients, and to prioritize advance care planning for patients undergoing high-risk surgery. Despite the recognized risk of performing surgery in high-risk patient populations, many patients do not have a complete understanding of the wide range of possible outcomes associated with surgery.[53a] The mental frameworks often employed by surgeons and their patients can contribute to both a lack of understanding of possible outcomes and the formation of a contractual obligation to engage in maximal life-sustaining measures after surgery.[53b-d] Both of these issues may result in provision of care that is not well-aligned with patient goals and preferences.

Communication frameworks exist that can assist in conducting preoperative conversations with patients considering high-risk surgery.[53e,f] The "Best Case/Worst Case" tool uses a shared decision-making model with a visual aid to explain the best case scenario, the worst case scenario, and the most likely outcomes related to both surgery and conservative management (Fig. 52.6).[53f] This tool allows the surgeon to elicit treatment preferences that are informed by realistic outcomes. Optimal use of the Best Case/Worst Case tool takes patient-specific comorbidities and risk factors combined with surgery-specific risk into account when explaining possible outcomes to patients considering high-risk surgery. A qualitative analysis of the Best Case/Worst Case tool using focus groups of both surgeons and older patients who had been involved in making a medical decision for themselves or their family members within the last year was conducted.[53f] From a patient perspective, the tool was seen as favorable overall in that it establishes a choice, allows visualization of distinct paths to help in decision making, and encourages deliberation based on a variety of treatment preferences. Surgeons pointed out that use of this tool provides a useful structure to guide the conversation, allows discussion of patient preferences, and may legitimize non-operative treatment options as still providing care rather than doing nothing. Use of tools such as this one may improve a patient's understanding of potential complications and consequences of choosing a

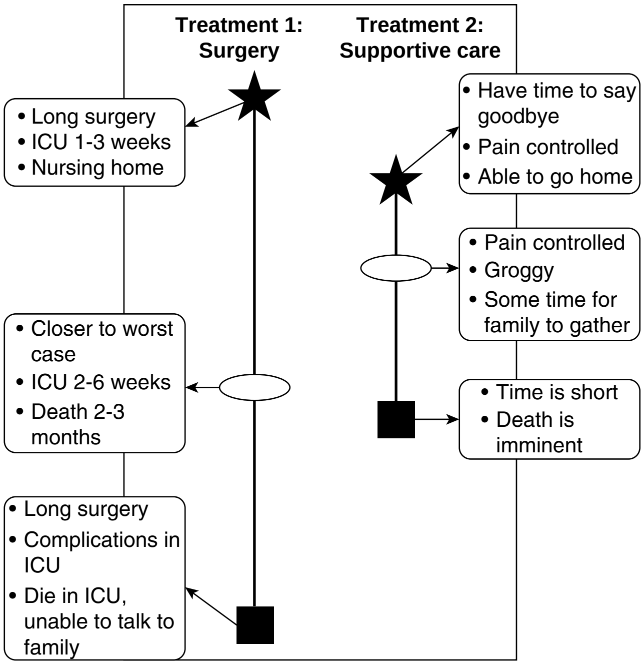

Fig. 52.6 The best case/worst case tool involves the drawing of a pen–and–paper diagram by the physician. A vertical bar depicts each treatment option, and the length of the bar represents the range of possible outcomes. A star represents the best case, a box the worst case, and an oval the most–likely outcome. The physician describes each "case" using narrative derived from clinical experience and relevant evidence and writes key points on the diagram. *ICU*, Intensive care unit. (Redrawn from Kruser J, Nabozny MJ, Steffens NM, et al. "Best case/worst case": Qualitative evaluation of a novel communication tool for difficult in–the–moment surgical decisions. *J Am Geriatr Soc*. 2015;63[9]:1805–1811.)

specific therapy, which allows them to elect the treatment option that is best aligned with his or her goals near the end of life.

Anesthetic Concerns in the Patient Receiving Palliative Care

PREOPERATIVE CONSIDERATIONS

A patient's decision-making capacity may change during a hospitalization or over time and should be assessed before seeking consent from the patient for anesthesia. As noted in Chapter 8, when a standing DNR order exists in a patient awaiting surgery, a discussion of the patient's goals and the creation of a plan for intraoperative and postoperative management that meets the patient's goals should occur prior to surgery. In the case of the perioperative reversal of a DNR order, a plan for when to reinstitute that order should be developed[53g] and discussed with the surgeon and nurse as appropriate.

A thorough preoperative evaluation of the patient's disease should also take place with attention to the patient's cognitive status, recent medications (including chemotherapy), presence of metastases, and wounds. Knowledge of the patient's preoperative functional status and prognosis may impact the anesthetic plan and also may inform an accurate assessment of risks and benefits. Details on special considerations in specific disease states such as cancer, COPD, and others are included in Chapter 32. Considering the number of patients receiving palliative care who may be on large doses of opioids perioperatively, anesthesiologists are advised to follow the guidelines in Chapter 51 regarding perioperative pain management.

INTRAOPERATIVE CONCERNS

Resuscitation status should be communicated to any perioperative providers caring for the patient. Consideration should be given to postoperative nausea and vomiting prophylaxis, and the care of fragile skin in this population. Patients may have coagulopathies, thrombocytopenias, or neutropenias that may preclude them from receiving regional or neuraxial anesthesia, thereby impacting their intraoperative pain management.

ANESTHETIC CHOICE AND CANCER

Recent studies have attempted to clarify the role of anesthesia in cancer progression and recurrence. Studies of the effect of regional anesthesia on those with cancer are mixed but suggest a possible mortality benefit,[53h] although meta-analyses have not found either a beneficial nor detrimental effect of regional versus general anesthesia regarding cancer recurrence.[53i] Additional discussion is available in Chapter 45. Studies that examine the choice of specific systemic anesthetics on cancer are mostly in vivo or in vitro, but available data also suggest differences in responses to tumor cells among the different drugs (Table 52.1).[53j]

POSTOPERATIVE COURSE

Standard postoperative care is adequate for most patients in palliative care. Risks for postoperative pain, delirium, and nausea and vomiting may be increased, depending on the individual patient. Providers should communicate any limitations in care and when limitations revert to their preoperative status.

Communication

Communication about goals of care and treatment preferences influence many outcomes in patients with serious illness. Better communication has been associated with improvement in quality of life, decreased use of life-prolonging therapies near the end of life, provision of care that is more consistent with patient preferences, and earlier hospice referrals.[53k] The American College of Physicians describes communication with seriously ill patients as a "low-cost, high-value intervention."[53k] The American College of Physicians recommends that communication be initiated early in the course of life-threatening illness, and ideally by a physician with an established relationship with the patient.[53k]

ADVANCE CARE PLANNING

The Patient Self-Determination Act, which took effect in the United States in 1991, requires healthcare providers and institutions to advise patients of their right to an

TABLE 52.1 Anesthetic Drugs and Host Defenses

DRUG	POTENTIAL EFFECT ON ANTITUMOR HOST DEFENSES
Ketamine	Reduces natural killer (NK) cell activity and the number in animal models
Thiopental	Reduces NK cell activity and the number in animal models
Propofol	Reduces NK cell number in animal models
Volatile agents	Inhibits interferon stimulation of NK cell cytotoxicity in animal models Reduces NK cell number in humans; is associated with worse outcomes when compared with local anesthesia for melanoma excision
Nitrous oxide	Associated with acceleration in the development of lung and liver metastases in animal models No effect on cancer outcomes after surgery for colorectal carcinoma in humans Inhibits the formation of hematopoietic cells that may be important for tumor cells

advance directive and to develop institutional policies and education regarding advance directives.[54] However, since the introduction of advance directives, multiple issues have been identified, such as amending preferences as the illness and circumstances change.[55-57] Understanding a patient's goals requires open communication with the patient and physician and sometimes repeated conversations to clarify and update the goals of treatment as the patient's condition changes. More information on advance directives and decision-making surrogates can be found in Chapter 8.

OUTCOMES OF ADVANCE CARE PLANNING

The landmark 1995 Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) was a 2-year prospective observational study, followed by a 2-year randomized trial of 9105 patients in five U.S. teaching hospitals, with the goal of improving end-of-life decision making.[14] The study enrolled patients with advanced stages of nine illnesses and a 6-month mortality of 45% to 48%. The observation period showed that 49% of patients who did not want cardiopulmonary resuscitation (CPR) did not have a written DNR order, and that the physicians were often unaware of the patients' wishes.[14] In the intervention, prognostic data were made available to physicians, and a nurse was available to facilitate information sharing, advance care planning, and pain assessment. This intervention did not have any negative impact on physician communication, pain, use of hospital resources, or other measured outcomes.[21] Although more advance directives were documented, only 14% of the patients spoke with a physician when completing their advance directive, and only 25% of the physicians were aware of their patients' advance directives a week after hospital admission.[61] Similar studies did not demonstrate that advance directives influenced the types of care or the resources used.[62,63] These studies suggest that efforts toward increasing advance directives alone are insufficient to drive any changes in care.

Many barriers exist to advance care planning, including timing, setting, and quality of communication. Even though physicians often perceive successful communication about treatment planning with patients, data suggest that patient perceptions of treatment options and prognosis often vary considerably.[63a] For example, between 50% and 75% of patients with incurable cancer perceived that chemotherapy, radiation therapy, or surgery could lead to survival.[63a] It is not clear whether this discordance results from failure in physician communication, inability of the patient to understand and accept the information presented, or a combination of the two. Many professional organizations suggest that end-of-life care planning should begin in the outpatient setting when the patient has approximately 1 year to live.[63a] However, in reality, these discussions often do not occur until much later in the patient's course, such as when an invasive intervention such as mechanical ventilation is needed.[63b]

A variety of factors prevent use of advance directives around the time of high-risk surgery,[63c-e] including surgeon perception.[53d] Over half of the surgeons in a national survey indicated that they would not operate on a patient who expressed a desire to limit life-sustaining interventions postoperatively.[63d] However, patients who have previously undergone high-risk surgery have indicated retrospectively that a greater preoperative emphasis on three critical points would have been helpful: (1) the need for surgery versus alternative treatment options, (2) expectations for postoperative recovery, and (3) use of perioperative advance directives.[53a] This study highlights the need for communication with patients and their families around the surgical management and represents an opportunity for anesthesiologists to play a role in facilitating these conversations.

PHYSICIAN COMMUNICATION SKILLS TRAINING

The physician's approach to communication about difficult issues can affect how patients and families perceive illness, death, and treatment options. These skills are being taught as part of medical school curriculum with increasing frequency, but retention of skills tends to be low.[63f] Most physicians are less comfortable discussing code status than they are with other topics, such as consent for procedures.[64] Between 40% and 75% of physicians, depending on their level of training, assess their own knowledge of delivering "bad news" as inadequate.[65] Despite the fact that the American Board of Surgery includes basic knowledge and skills in palliative care as a requirement for board certification in surgery,[65a] only 9% of surveyed surgical residents believed they "received adequate training in palliation" during residency.[66] Similarly, as many as 90% of internal medicine residents expressed a desire for additional training in discussing topics such as DNR orders.[67] Despite this lack of training, residents often are the ones to talk about these issues with patients,[68] highlighting the importance of education in this area.

PHYSICIAN COMMUNICATION SKILLS

Physicians often rate their communication skills favorably, but surveys of other practitioners and of patients suggest that physicians may not be able to self-assess accurately. One study in an ICU showed that 90% of surgeons were satisfied with their communication skill concerning prognosis, but only 23% of intensivists and 3% of nurses rated the same skill favorably.[69] Similarly, patients' perceptions of their cancer stage and prognosis were often incorrect in one study, although oncologists thought they were clear in their explanations of the illness.[70] Recordings of physician discussions with patients and families show that physicians focus on technical detail, avoid emotional topics, and tend to dominate the conversations,[71] despite increased family satisfaction when the family spoke more and physicians exhibited more supportive behaviors.[71] Even when a conversation takes place between a physician and a patient, the physician and patient may not agree on the outcome. One study of patients with metastatic cancer showed that physicians misunderstood their patients' preferences for CPR 30% of the time.[72] Currently, no comparable studies regarding anesthesiologists have been conducted. These findings highlight the importance of assessing a patient's understanding of his or her disease process before a procedure is performed or during an ICU stay.

The Surgical "Contract"

When caring for surgical patients, it is important to understand the conceptual frameworks that frequently influence both providers and patients in their approach to care. First, many patients perceive that surgery will "fix" their acute abnormality and restore normalcy to their lives,[53f] rather than potentially contribute to further functional or cognitive decline. The potential for the latter problems is rarely discussed preoperatively. In addition, the relationships between surgeons and their patients are unique from other relationships in medicine, because many surgeons perceive an implicit "contractual" agreement to pursue maximal life-sustaining measures after surgery.[53c,d,72a] Surgeons are said to subscribe to a covenantal ethic, meaning that the surgeon takes on individual responsibility for the patient's life once he or she performs surgery.[72a] An ethnographic study examining differences in end-of-life management of surgical patients in three ICUs—one unit run by trauma surgeons, one unit co-managed by surgeons and intensivists, and one unit run by intensivists—identified divergent priorities between surgeons and intensivists. While many intensivists considered use of scarce resources more globally in their decision making, surgeons tended to focus on the individual patient only and delay withdrawal of life-sustaining treatment even when it was requested by family.[72a] Surgeons and intensivists often also delivered differing messages regarding treatment and prognosis.[72a] A study evaluating recorded preoperative conversations conducted by surgeons performing high-risk surgery found that surgeons often described high-risk surgery as "big surgery" and focused on the technical aspects of surgery during their preoperative conversations.[53b] If they discussed need for life support after surgery, they focused on standard recovery rather than potential longer-term complications (e.g., prolonged mechanical ventilation or dialysis). Furthermore, while many surgeons perceived that a contractual agreement to pursue aggressive postoperative care had been made, only rarely did they make this contract explicit with their patients.[53b] Other communication breakdowns may occur at the level of the patient (i.e., anxiety, fear, or inability to understand) or the medical system (i.e., time constraints, lack of advance care planning) and also contribute to decisions to proceed with nonbeneficial surgery.[53e] Having a good understanding of these unique communication challenges in surgical patients at the end of life may help to facilitate communication with patients, families, and the care team.

WHAT DO FAMILIES CONSIDER IMPORTANT IN END-OF-LIFE COMMUNICATION?

A majority of family members consider trust in the treating physician and truthful communication about the patient's illness as two of the most important factors in receiving quality end-of-life care.[73] Families have greater satisfaction when a higher level of decision making is shared.[74] In family meetings, family satisfaction increases with the number of empathetic statements made by a physician during a meeting.[75] Virdun and associates conducted a meta-synthesis of 16 qualitative studies examining factors that patients and families describe as important during inpatient end-of-life care.[75a] Within the theme of effective communication and shared decision making, family members identified honest and clear communication using simple, understandable language; provision of information necessary to help make decisions; and engaging both the patient and family members in care planning as priorities.[75a]

A variety of patient and family preferences influence the quantity of information desired and how to receive it. These preferences may be informed by a combination of personal, cultural, and family characteristics; however, physicians should not assume a preference based on a patient's race or ethnicity.[76] Many practitioners use a question such as, "How much would you like to know?", [77] although no studies of patient perceptions of that approach have been conducted. One study of patients with cancer indicated that some patients' preferences for involvement in decision making changed over the course of the illness.[78] A few studies have noted that caregivers wanted more information than the patients.[79] Some patients may indicate that they do not want to know about their condition and name a surrogate decision maker instead.

SPIRITUALITY AT THE END OF LIFE

Spirituality refers to the ways in which a person expresses meaning or purpose and affects an individual's sense of connectedness to the world around them. Religion may be a component of spirituality for some people, but many other aspects of spirituality also exist. Swinton and colleagues conducted a qualitative study where patients, family members, and clinicians involved in the care of 70 patients dying in the ICU underwent semistructured interviews.[79a] Respondents perceived dying as a spiritual process. They reflected that spirituality comprises an important part of a patient's narrative before, during, and after death. Serious illness and the prospect of death can bring a number of spiritual issues to the foreground for patients and families, from questioning the meaning of one's life to a religion's teaching on specific medical interventions.[80] Patients typically want physicians to ask about their spiritual preferences[81] and describe their spiritual needs as frequently remaining unmet.[82] A simple screening question such as, "Is religion or spirituality important in your life?" has been proposed and may help identify patients in whom a spiritual need exists. Asking about religion and spirituality may provide a context for the healthcare team, since many patients and families make decisions based these beliefs.[83] Physician understanding of the reasoning behind their patients' decisions is likely to improve end-of-life care.

COMMUNICATION FRAMEWORKS

The prior studies, which demonstrate frequent misunderstandings and poor communication, emphasize the need for an understanding of the importance of effective communication among all participants.[85] A number of frameworks have been developed to aid physicians in discussions with patients and families.[86-88] No study has compared their relative effectiveness on patient or family outcomes, and very few assessed the effect of a specific communication framework on outcomes.[77] Commonalities in the approaches include active listening, validating patient concerns, and assessing understanding. A recommended comprehensive conversation guide developed by synthesizing data collected in multiple qualitative studies includes the following elements: set up the conversation, assess understanding and preferences, share prognosis, explore key topics (i.e., goals, fears and worries, sources of strength, critical abilities, tradeoffs, and family), close the conversation, document your conversation, and communicate with key clinicians (Fig. 52.7).[88a]

Family Meetings

Family conferences in the ICU have increasingly been used to facilitate information sharing between families and providers. In the ICU setting, meetings held within 72 hours of admission have shown decreased lengths of stay without increased mortality.[89] One of the few studies that evaluated a standardized communication approach was a single-site study of families of patients who were seriously ill and randomized to either a standardized communication template with a bereavement brochure or the standard care.[87] The communication intervention structured around the mnemonic of VALUE (value, acknowledge, listen, understand, elicit questions) emphasizes empathy, understanding of the patient as a person, and allowing family members to ask questions.[87] Family members in the study arm had decreased symptoms of psychological distress in a survey 3 months later (Box 52.2).[87]

Many physicians struggle with how to begin family meetings. Common approaches include: introducing the family and team members, eliciting the level of understanding from family members, and briefly summarizing the purpose of the meeting; for example, "What have you been told about what's going on with your dad?".

Breaking Bad News

The six-step SPIKES (setting, perception, invitation, knowledge, empathy, sequelae) protocol is a framework for breaking bad news. Several of the elements, such as finding a quiet meeting space, asking what the patient or family understands, and making a plan for the future, apply in many situations (Box 52.3).[86] A meta-synthesis of available qualitative data suggested that breaking bad news is a skill that requires the provider to reassess and adapt the conversation based on a number of factors including the provider-patient relationship, responses from the patient and family, the environment, and cultural or social factors.[89a]

Responding to Emotion

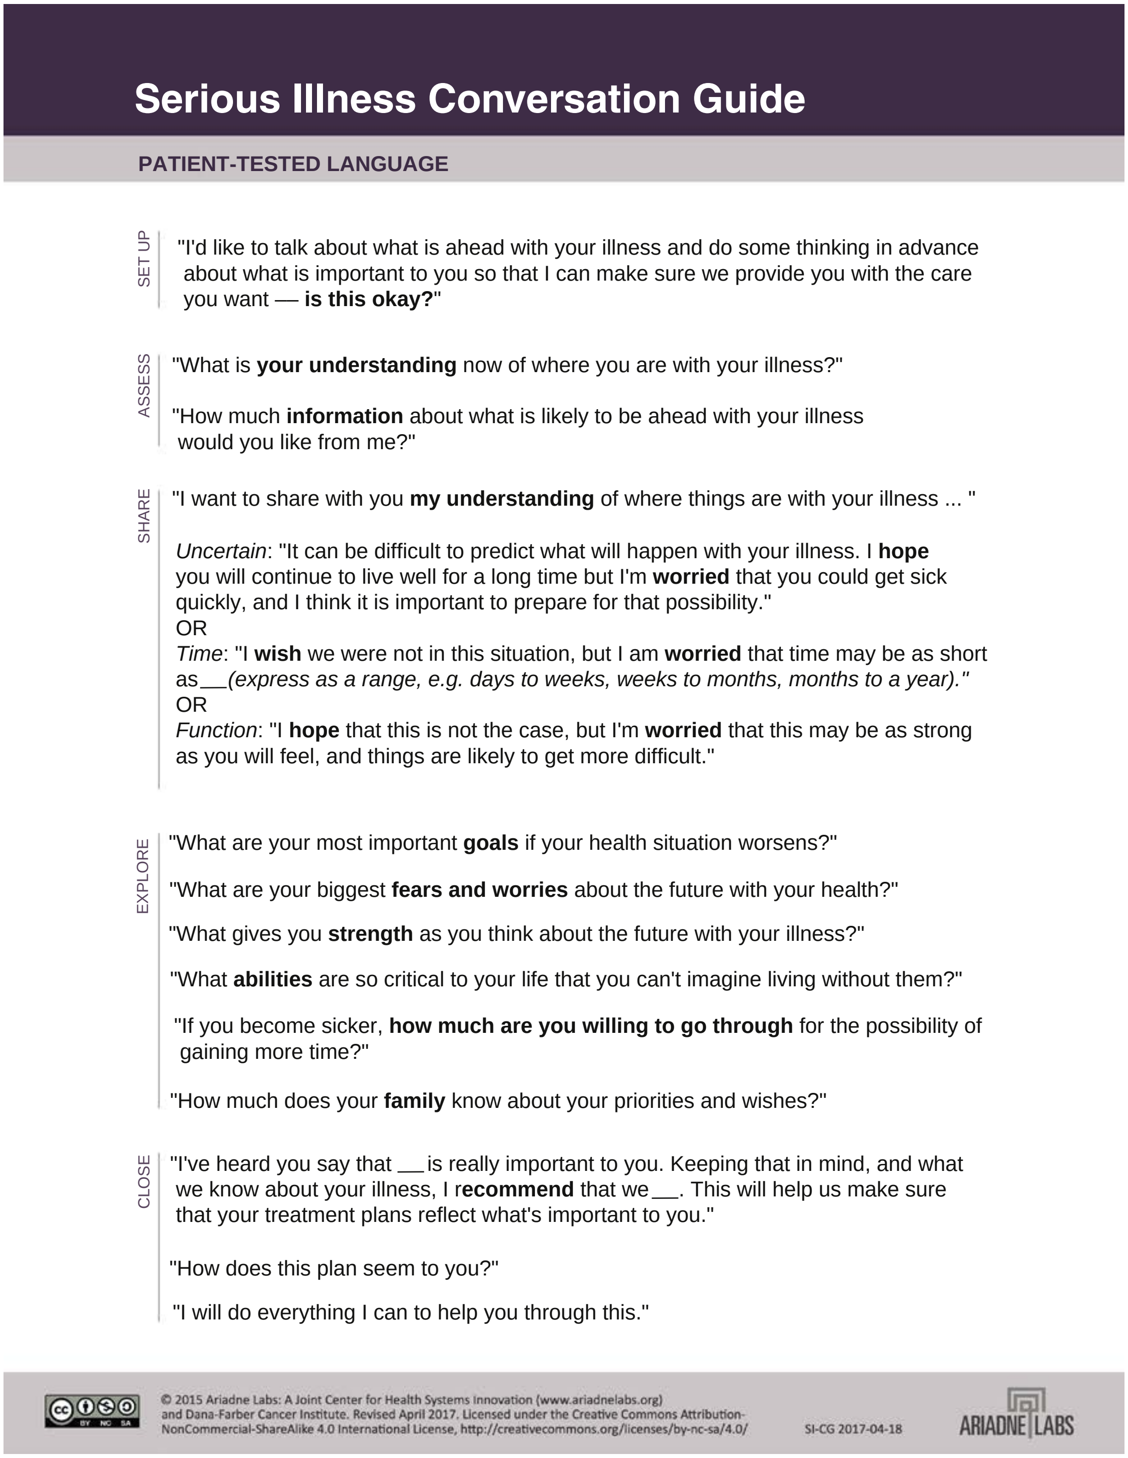
The NURSE (name, understand, respect, support, explore) protocol is a framework for responding to emotion, including anger. Patient and family anger directed toward healthcare providers is common in the setting of serious illness.[90] Crucial concepts in responding to anger include not becoming defensive or personalizing the anger, respectfully listening, and setting appropriate boundaries for safety.[90] Although difficult to accomplish in the moment, viewing anger as a coping mechanism in the grieving process is often helpful (Box 52.4).[91]

Requests for Nondisclosure

Family members may ask physicians to withhold a diagnosis from the patient. The cultural norms for disclosing a patient's diagnosis vary widely among cultures and countries. In the United States, the culture of disclosure has rapidly changed, and now most physicians expect to disclose the prognosis to the patient.[92] No evidence is available that recommends how to deal with requests for nondisclosure, but expert opinions recommend empathetically responding to the family member, trying to understand the family's concerns about disclosing the prognosis, and asking the patient how and if he wants to be involved. For example, "Some people want to be told about any health issues and make their own decisions, while others prefer for a family member to be told the medical information and to make the decisions. What would you like?"[93]

Time-Limited Trials

In cases where the benefit of a clinical intervention is unclear for a specific patient, a time-limited trial, in which



Serious Illness Conversation Guide

PATIENT-TESTED LANGUAGE

SET UP

"I'd like to talk about what is ahead with your illness and do some thinking in advance about what is important to you so that I can make sure we provide you with the care you want — **is this okay?**"

ASSESS

"What is **your understanding** now of where you are with your illness?"

"How much **information** about what is likely to be ahead with your illness would you like from me?"

SHARE

"I want to share with you **my understanding** of where things are with your illness ... "

Uncertain: "It can be difficult to predict what will happen with your illness. I **hope** you will continue to live well for a long time but I'm **worried** that you could get sick quickly, and I think it is important to prepare for that possibility."
OR
Time: "I **wish** we were not in this situation, but I am **worried** that time may be as short as___*(express as a range, e.g. days to weeks, weeks to months, months to a year)."*
OR
Function: "I **hope** that this is not the case, but I'm **worried** that this may be as strong as you will feel, and things are likely to get more difficult."

EXPLORE

"What are your most important **goals** if your health situation worsens?"

"What are your biggest **fears and worries** about the future with your health?"

"What gives you **strength** as you think about the future with your illness?"

"What **abilities** are so critical to your life that you can't imagine living without them?"

"If you become sicker, **how much are you willing to go through** for the possibility of gaining more time?"

"How much does your **family** know about your priorities and wishes?"

CLOSE

"I've heard you say that ___ is really important to you. Keeping that in mind, and what we know about your illness, I **recommend** that we___. This will help us make sure that your treatment plans reflect what's important to you."

"How does this plan seem to you?"

"I will do everything I can to help you through this."

the physician and patient or family agree to reevaluate the benefit after a specified period, may be helpful.[94] Time-limited trials give families a sense of when the health-care team expects to know whether an intervention is helping and creates the expectation that the issue will be readdressed.

RESUSCITATION STATUS

Outcomes of Cardiopulmonary Resuscitation

CPR was introduced around 1960, initially as a treatment for intraoperative events[95] and then expanded outside the surgical unit. Outcomes of CPR have improved, with over

BOX 52.2 VALUE: Framework for End-of-Life Conferences

Value: Value and appreciate what the family member says. "Thank you for helping me understand how your husband's condition has changed over the past year."

Acknowledge: Acknowledge emotions. "This is often a sad time for families."

Listen: Actively listen. Remember to be silent and to give the family member time to speak.

Understand: Gain an understanding of the patient. Ask who the patient is as a person. "Can you tell me about your father, what kind of person he is and what's important to him?"

Elicit questions: Ask family members if they have questions. "We have discussed a lot of information. Do you have any questions?"

Data from Lautrette A, Darmon M, Megarbane B, et al. A communication strategy and brochure for relatives of patients dying in the ICU. *N Engl J Med.* 2007;356:469–478.

BOX 52.3 SPIKES: Framework for Breaking Bad News

Setting: Arrange for a quiet, private space large enough for all participants.

Perception: Assess the participants' understanding. "What have the doctors told you about your wife's illness?"

Invitation: Ask how much information is desired. "Some people like all the details, others just like the big picture. What would you like?"

Knowledge: Tell the participants what is known, using language that is easy to understand and avoiding the use of complex medical phrases.

Empathy: Acknowledge emotions. "I wish things were different."

Sequelae: Agree on the next steps. "Let's meet tomorrow afternoon so I can update you on her condition."

Data from Baile WF, Buckman R, Lenzi R, et al. SPIKES–A six-step protocol for delivering bad news: application to the patient with cancer. *Oncologist.* 2000;5:302–311.

BOX 52.4 NURSE: Framework for Dealing with Emotion

Name: State the emotion you believe the patient or caregiver is exhibiting. "It seems like you are angry."

Understand: Empathize with and legitimize the emotion. "I can't imagine how hard this must be for you."

Respect: Praise the patient or caregiver for his or her strength. "You've done so much for your mother during this difficult time."

Support: Show support. "I want to help."

Explore: Ask the patient or caregiver to elaborate on the emotion. "Can you help me understand what was so frustrating today?"

Data from Back AL, Arnold RM, Baile WF, et al. Approaching difficult communication tasks in oncology. *CA Cancer J Clin.* 2005;55:164–177.

half the patients who suffer in-hospital cardiac arrest surviving the initial resuscitation and nearly one quarter surviving to discharge.[96] Survival is better for patients with a shockable initial rhythm (37%) when compared with pulseless electrical activity (12%) or asystole (11%),[96a] with time to defibrillation representing a critical factor in patient outcome.

Approximately 85% of cardiac arrests in surgical patients occur postoperatively, and this patient population may have a higher likelihood of survival than other groups of patients.[97,98] In one large study of older surgical patients who survived to discharge after in-hospital CPR, approximately one half had moderate-to-severe neurologic defects[99] and 60% were alive 1 year later.[99] Induced mild hypothermia improves neurologic outcome after cardiac arrest, but benefits are better demonstrated in the out-of-hospital arrest population.[99a] Data increasingly suggest that there are gender differences between outcomes after cardiac arrest. A study comparing outcomes in men and women after cardiac arrest showed that women who survived to discharge after cardiac arrest had worse cognitive, functional, and psychiatric outcomes after multivariate adjustment for multiple confounders.[99b]

Resuscitation Status Discussions

Discussion of resuscitation status can be challenging to some providers.[64] Anesthesiologists may be involved in conducting discussions related to resuscitation status with patients in the ICU or in the perioperative period. Ideally, the discussion about code status takes place in the context of a conversation about the patient's overall health and goals. For example, one patient might decide on life prolongation as a goal, in which case a physician might recommend resuscitation attempts even if unlikely to succeed, whereas another patient with the same illness might prioritize physical independence as a goal, in which case the physician might recommend a DNR order to decrease the likelihood of prolonged ICU time or an unacceptable physical status. The impact of this approach is unknown. A small simulated study that played a standardized video of a code status discussion to cancer patients showed no difference between asking the patient his or her desired resuscitation status or making a suggestion for DNR order.[100] The few studies that formally examine the best way to approach discussions regarding resuscitation do not clearly demonstrate a single best approach.[95] For example, one study examined using the terminology "allow natural death" instead of "do not resuscitate" with terminal cancer patients and did not show that either term was favored over the other.[100a]

Perioperative Limitations on Treatment

The American Society of Anesthesiologists has published guidelines related to orders for the limitation of treatment in the perioperative setting.[101] The ethics of perioperative DNR orders are discussed more comprehensively in Chapter 8.

Prognosis

Multiple studies have examined the ability of physicians to prognosticate survival for a given patient. In a meta-analysis of eight studies in patients with a median survival of 4 weeks, physicians overestimated the prognosis by approximately 30%.[108] Predictions were more accurate in patients with poorer performance status.[108] In a prospective cohort study of 365 physicians and 504 patients receiving hospice care, the physicians overestimated survival by a factor of 5, and 63% of their predictions were overestimates.[109] The longer a physician knew a patient, the more difficult it was for that physician to prognosticate.[109] Physicians in the ICU tend to be overly pessimistic. In a study of 851 patients receiving mechanical ventilation, only 71% of patients for whom a physician estimated a likelihood of survival of less than 10% at some point during their stay in the ICU died in the ICU.[110] A meta-analysis suggested that physicians are more accurate at predicting mortality than algorithmic scoring systems (described in the "Prognostic Tools" section) in the first 24 hours after ICU admission; however, neither physicians nor scoring systems are reliably accurate for individual patients.[111] Overall, physician estimates do correlate with survival[112] and are more accurate in predicting mortality than other outcomes such as return to cognitive baseline.[112a] For example, a study of 521 patients in a MICU found that physicians and nurses were unable to predict satisfaction with the quality of life 6 months after admission. In general, nurses tended to be more pessimistic than physicians and suggested withdrawal of life-sustaining treatment more often in patients who ultimately survived (Figs. 52.8 and 52.9).[113] Prognostic tools that include clinician assessment are better than tools that rely on objective data alone, but the best predictions arise when multiple providers (physicians and/or nurses) agree on the prognosis.[113a]

Difficulty with prognostication has led some physicians to avoid giving any kind of timeframe to eliminate the possibility of being wrong.[114,115] However, 87% of 179 surrogate decision makers wanted the physician to give a prognosis, even if it was uncertain.[116] Most understood the inherent unpredictability of prognostication and preferred that physicians make the prognostic uncertainty clear during the discussion.[116] Prognosis, even in the face of uncertainty, can help families prepare for bereavement and make important decisions about coordinating work, visitors, and finances.[116] Good data suggesting how to present prognoses to patients are not available. One approach to prognostication involves giving ranges such as hours to days, days to weeks, weeks to months, and months to years, with those categories roughly tracking with functional status. These ranges, along with an explanation from the physician about the difficulty of prognosticating, can often give families sufficient guidance with which to make important decisions. However, interpretation of a given prognosis may vary with the patient and family. One study that gave surrogate decision makers in the ICU hypothetical physician statements about prognosis and asked them to interpret them showed that surrogates tended to be optimistic, especially with worse prognoses.[117]

DISEASE TRAJECTORIES

Most disease trajectories can be included in one of the following functional categories: sudden extreme disability or near death; a period of good functionality, followed by a rapid, steady decline; a waxing and waning course with periods of decompensation followed by improvements; and a slow decline, starting at a low functional level (Fig. 52.10).[119] These frameworks can be useful when discussing prognoses with patients, particularly in talking to patients with conditions that are difficult to predict such as COPD and CHF.

PROGNOSTIC TOOLS

Multiple web-based prognostic tools exist, but they are typically specific to particular cancers. But an important consideration is that the type of cancer is actually less important than a variety of patient factors (e.g., functional status and laboratory values) as the disease becomes more advanced (Fig. 52.11).[120] In general, a patient with cancer who spends more than half of the day in bed has a median survival of 6 months (Box 52.5).[121]

Multiple tools, which are covered in depth in Chapter 84, have been proposed to help the clinician predict mortality in the ICU. These tools may be more useful in the research setting than for prediction of outcome in an individual patient.

Many conditions have courses that are difficult to predict. Table 52.2 gives characteristics associated with noncancer patients such as heart failure, dementia, hepatic cirrhosis, and COPD, with a median survival of 6 months or less,[122] although it should be noted that the prognostic accuracy of these factors is not known.

Congestive Heart Failure

CHF often has a waxing and waning course. The Seattle Heart Failure Model estimates mean 1- to 3-year survival but does not appear to be able to predict whether individual patients are in the last year of life.[123] Factors associated with a poor prognosis include hospitalization, tachycardia, hypotension, decreased ejection fraction, and increased creatinine level.[124] In patients

BOX 52.5 Cancer Presentations with a Median Survival of 6 Months or Less

Solid Cancers in General

Any locally advanced or metastatic solid cancer with one or more of the following presentations:

- Patient spends more than one half of the day in bed
- Serum calcium > 11.2 mg/dL
- Episode of extremity venous thromboembolism or pulmonary embolism
- Two or more brain metastases plus intracranial metastases
- Spinal cord compression with decreased ability to walk
- Malignant pericardial effusion

Carcinoma of Unknown Primary Origin

Any metastatic adenocarcinoma or undifferentiated carcinoma of unknown primary origin with one or more of the following presentations:

- Patient is ambulatory and can care for him or herself but cannot work
- Hepatic, bone, or adrenal metastases
- Recurrence of disease after chemotherapy
- Serum albumin < 3.5 mg/dL or weight loss of ≤ 10% in 6 months

Modified from Salpeter SR, Malter DS, Luo EJ, et al. Systematic review of cancer presentations with a median survival of six months or less. *J Palliat Med.* 2012;15:175–185.

hospitalized for acute decompensation of heart failure, older age and COPD were associated with decreased 1-year survival.[125]

Dementia

The course of dementia is difficult to predict, and a patient's 6-month mortality is higher once the patient develops the common problems of infection and an inability to eat.[126] Probability of death within 6 months increases with advancing age, shortness of breath, immobility, and insufficient oral intake, among other presentations.[127]

Chronic Obstructive Pulmonary Disease

The BODE Index, which is used to predict the risk of death in COPD, measures **b**ody mass index, airflow **o**bstruction, **d**yspnea, and **e**xercise capacity[128]; however, its use of a 6-minute exercise capacity test makes it impractical for the bedside anesthesiologist. More than 3 days of mechanical ventilation and an inability to extubate the trachea successfully suggest a poor prognosis.[129]

Liver Disease

In decompensated liver disease, the Model for End-Stage Liver Disease score is often used to predict a prognosis.[130] Hepatic encephalopathy and hepatorenal syndrome are also predictors of a poor prognosis.[130,131]

Renal Disease

Patients with chronic kidney disease on dialysis will live 16% to 33% as long as age- and sex-matched patients who are not on dialysis.[132] Probability of survival at 10 years for patients on dialysis who are older than 65 years of age is 3.1%.[132] Poor functional and nutritional status, as well as comorbid conditions, suggest a poor prognosis.[132] Withdrawal of dialysis accounts for up to 20% of deaths in patients on dialysis each year, and the average patient lives 8 to 12 days after dialysis withdrawal.[133]

SYMPTOM MANAGEMENT

Alternative Routes of Drug Delivery

Many patients near the end of life are unable to swallow oral medications as a result of oral lesions, nausea, the dying process, or other reasons. Many patients in palliative and hospice care have difficult intravenous access as a result of frequent medical care, dehydration, or other issues. To avoid multiple attempts at intravenous cannulation, palliative medicine practitioners and most hospices use subcutaneous infusions for the delivery of medications, especially opioids.[136,137] An assumption of safety is based, in part, on studies showing that many intramuscular injections are actually administered into the subcutaneous tissue.[138] In addition, other types of drugs such as benzodiazepines, some antiemetic medications, antibiotics, neuroleptics, and even fluids can be subcutaneously administered in the palliative care setting.[136,137,138a] While the subcutaneous administration of opioids is safe, the optimal conversion ratio from one route to another is a subject of debate.[139] Other studies support the transmucosal, sublingual, and rectal administration of opioids.[139] Finally, neuraxial drug delivery via continuous epidural infusions or intrathecal pumps can be utilized, particularly for intractable pain.[139a]

Pain

Pain management in patients who are seriously ill can be quite different from other patients with pain. Some of these patients have pain that is best managed by a pain management specialist, and some will need adjuvant medications (Table 52.3). In cancer patients, 15% to 90% with solid tumors have pain, depending on the type and stage of cancer, as well as the age, race, and sex of the patient.[144] Most cancer pain is due to the cancer itself, but approximately one fifth of patients develop pain related to the cancer treatment.[145] The majority of cancer pain can be managed with the WHO "Cancer Pain Stepladder."[146] Zech published a prospective study of 2118 cancer patients using this stepladder during which 76% of the patients received pain relief with minimal side effects.[146] However, pain management may be significantly more challenging for patients with advanced cancer. Sixty to 90% of this population report pain that significantly impacts function, mood, and sleep. Pain of this severity may benefit from more advanced techniques such as interventional pain medicine (see Chapter 51),[146a,b] psychological interventions,[147] or palliative chemotherapy or radiation therapy.

Bone Pain

Breast, lung, kidney, and prostate cancers frequently metastasize to the bones.[148] Patients with metastatic disease can have both osteoblastic and osteolytic bony lesions leading to severe pain.[149] Multiple targets for bone pain are possible, but no clear consensus has been reached on the best treatment methods.[150] Hormonal therapy is effective in breast, prostate, and endometrial cancers. Interventional techniques such as intrathecal catheters

TABLE 52.2 Presentations of Noncancer Diagnoses With a Median Survival of 6 Months or Less

Diagnosis	Presentation
HEART FAILURE	
Hospitalization for moderate-to-severe symptomatic heart failure, NYHA Class III or IV, with three or more of the presentations listed.	■ Age >70 years ■ LVEF ≤20% ■ Serum BNP > 950 pg/mL ■ Cardiac troponin I > 0.4 ng/mL ■ CRP >3.5 mg/L ■ Fourth hospitalization for heart failure or repeat hospitalization within 2 months ■ Dependency for two or more activities of daily living or need for home care after hospital discharge ■ Weight loss ≤2.3 kg within 2 months, or serum albumin < 2.5 g/dL ■ History of cardiogenic shock, ventricular or supraventricular arrhythmia, cardiac arrest, CPR, or mechanical ventilation ■ Systolic blood pressure < 110 mm Hg ■ Serum creatinine > 2 mg/dL or BUN > 40 mg/dL ■ Serum sodium < 135 mEq/L ■ Peripheral vascular disease or cerebrovascular disease ■ Other comorbid illness, such as diabetes mellitus, dementia, COPD, cirrhosis, and cancer, among others
DEMENTIA	
Advanced dementia with dependency in all activities of daily living, bedbound status, urinary and bowel incontinence, decreased ability to communicate verbally, and admission to a hospital or skilled nursing facility with one or more of the presentations listed.	■ BMI < 18.5 kg/m^2, decreased oral intake, or significant weight loss ■ Presence of at least one pressure ulcer ■ Evidence of at least one comorbid illness ■ Male sex plus > 90 years of age ■ Placement of a feeding tube attributable to inability to eat or history of aspiration
HEPATIC CIRRHOSIS	
Decompensated hepatic cirrhosis and one or more of the presentations listed.	■ MELD score ≥21
Decompensated hepatic cirrhosis with hospitalization for an acute illness related to liver disease and one or more of the presentations listed.	■ MELD score ≥18 ■ Hospitalization in an intensive care unit related to severe decompensation of liver disease with hypotension requiring the use of pressors, serum creatinine > 1.5 mg/dL, or evidence of jaundice ■ Evidence of hepatopulmonary syndrome or rapidly progressive hepatorenal syndrome
CHRONIC OBSTRUCTIVE PULMONARY DISEASE	
Hospitalization for a severe COPD exacerbation, with PaO_2 ≤55 mm Hg, $PaCO_2$ ≥50 mm Hg, and supplemental oxygen dependence, with three or more of the presentations listed.	■ Age >70 years ■ Evidence of right-sided heart failure ■ Repeat hospitalization for COPD within 2 months ■ History of intubation and mechanical ventilation ■ Required considerable assistance and frequent medical care and/or dependence for three or more activities of daily living before hospitalization ■ Need for home care after hospital discharge ■ Malnutrition (weight loss of ≥ 2.3 kg, serum albumin < 2.5 g/dL or BMI < 18 kg/m^2 ■ Serum creatinine > 2 mg/dL

BMI, Body mass index; *BNP,* brain natriuretic peptide; *BUN*, blood urea nitrogen; *COPD,* chronic obstructive pulmonary disease; *CPR*, cardiopulmonary resuscitation; *CRP,* C-reactive protein; *LVEF,* left ventricular ejection fraction; *MELD,* Model for End-Stage Liver Disease; *NYHA,* New York Heart Association; *$Paco_2$*, partial arterial pressure of carbon dioxide; *Pao_2*, partial arterial pressure of oxygen. TABLE 52.3 Adjuvant Analgesics in the Management of Cancer Pain

	Examples	Comment
MULTIPURPOSE ANALGESICS		
Glucocorticoids	Dexamethasone, prednisone	Are used for bone pain, neuropathic pain, lymphedema pain, headache, and bowel obstruction
ANTIDEPRESSANTS		
TCAs	Desipramine, amitriptyline	Are used for opioid-refractory neuropathic pain; often used with comorbid depression; secondary amine compounds (e.g., desipramine) have fewer side effects and might be preferred
SNRIs	Duloxetine, milnacipran	Good evidence exists for their use in some conditions but are overall less effective than TCAs; better side-effect profile than TCAs and are often tried first
SSRIs	Paroxetine, citalopram	Evidence for their use is scarce; if pain is the target, then other subclasses are preferred

TABLE 52.3 Adjuvant Analgesics in the Management of Cancer Pain—cont'd

Other	Bupropion	Little evidence exists for its effectiveness but less sedating than other antidepressants; is often tried early when fatigue or somnolence is a problem
α_2-Adrenergic agonists	Tizanidine, clonidine	Are seldom used systemically because of side effects, but tizanidine is preferred for a trial; clonidine is used in neuraxial analgesia
Cannabinoid	THC/cannabidiol, nabilone, THC	Good evidence exists for THC/cannabidiol when used in cancer pain; evidence is scarce for other commercially available compounds
TOPICAL AGENTS		
Anesthetic	Lidocaine patch, local anesthetic creams	Sometimes used in localized pain
Capsaicin	8% patch; 0.25%-0.75% creams	High concentration patch is indicated for postherpetic neuralgia
NSAIDs	Diclofenac and others	Evidence exists for their use in focal musculoskeletal pains
TCA	Doxepin cream	Is used in treating itching; can be tried for pain
Others		Compounding creams with various drugs have been empirically tried, but no evidence exists for effectiveness
USED FOR NEUROPATHIC PAIN		
Multipurpose drugs	As above	As above
ANTICONVULSANTS		
Gabapentinoids	Gabapentin, pregabalin	Are used first for opioid-refractory neuropathic pain unless comorbid depression; may have multipurpose uses in view of the evidence in postsurgical pain; both drugs act as N-type calcium channel blockers in the CNS, but individuals vary in response to one or the other
Others	Oxcarbazepine, lamotrigine, topiramate, lacosamide, valproate, carbamazepine, phenytoin	Evidence is scarce for all drugs listed; newer drugs are preferred because of reduced side-effect liability, but individual variation is great; all drugs are considered for opioid-refractory neuropathic pain if antidepressants and gabapentinoids are ineffective
SODIUM-CHANNEL DRUGS		
Sodium-channel blockers	Mexiletine, intravenous lidocaine	Good evidence exists for intravenous lidocaine
Sodium-channel modulator	Lacosamide	New anticonvulsant with very scarce evidence of analgesic effects
GABA AGONISTS		
GABA_A agonist	Clonazepam	Evidence is scarce but used for neuropathic pain with anxiety
GABA_B agonist	Baclofen	Evidence for the treatment of trigeminal neuralgia is the basis for trials in other types of neuropathic pain
N-methyl-D-aspartate inhibitors	Ketamine, memantine, and others	Evidence is scarce for ketamine, but experience is positive with intravenous use in advanced illness or pain crisis; little evidence exists for oral drugs
USED FOR BONE PAIN		
Bisphosphonates	Pamidronate, ibandronate, clodronate	Good evidence exists for their use; similar to NSAIDs or glucocorticoids, usually considered first-line treatment; also reduces other adverse skeletal-related events; concern about osteonecrosis of the jaw and renal insufficiency might restrict its use
Calcitonin		Evidence is scarce but is usually well tolerated
Radiopharmaceuticals	Strontium-89, samarium-153	Evidence is good, but their use is restricted because of bone-marrow effects and the need for expertise
USED FOR BOWEL OBSTRUCTION		
Anticholinergic drugs	Hyoscine compounds, glycopyrronium	Along with a glucocorticoid, are considered first-line adjuvant treatments for nonsurgical bowel obstruction
Somatostatin analog	Octreotide	Along with a glucocorticoid, is considered a first-line adjuvant treatment for nonsurgical bowel obstruction

CNS, Central nervous system; *GABA,* gamma-aminobutyric acid; *NSAIDs,* nonsteroidal antiinflammatory drugs; *SNRIs,* selective noradrenaline reuptake inhibitors; *SSRIs,* selective serotonin reuptake inhibitors; *TCAs,* tricyclic antidepressants; *THC,* tetrahydrocannabinol. Modified from Portenoy RK. Treatment of cancer pain. *Lancet.* 2011;377:2236–2247.

may be appropriate in some patients.[151] Palliative radiotherapy can be helpful for patients with bone metastases, although pain relief may take several weeks.[152] Dexamethasone orally, subcutaneously, or intravenously is commonly recommended for bone pain by expert consensus, although only a few small studies support its use.[154] Bone-modifying agents, such as zoledronic acid or pamidronate, have shown benefit for bony pain in some cancers and should be considered when appropriate from an oncologic standpoint.[148,155] Nonsteroidal antiinflammatory drugs are helpful in alleviating cancer pain, although their advantage when combined with opioids is less clear.[156] More advanced interventions such as epidural steroid injections, vertebroplasty/kyphoplasty, or surgery may be indicated.[156a]

Neuropathic Pain

Between 17% and 28% of patients with advanced cancer have neuropathic pain.[157] More information on neuropathic pain, the use of lidocaine and ketamine, and other adjuvant medications is available in Chapters 25 and 51 (see Table 52.3). As always, a patient's life expectancy should be considered, because some medications may be difficult to titrate adequately in a short period.

Pain in the Intensive Care Unit

In the ICU, pain is common and attributable to many factors such as surgical wounds, placement of invasive monitoring devices, and immobility.[158] Pain is also difficult to assess in the ICU because the trachea is intubated or the patient is unable to speak. The Behavioral Pain Scale[159] and the Critical Care Pain Observation Tool[160] are validated methods of assessing pain in the ICU population.[161] Commonalities among the tools include assessment of facial expression, body movement, and synchrony with ventilation. In the SUPPORT trial, pain was poorly controlled among those who died in the hospital, with half of the surrogates indicating that their family member had moderate-to-severe pain for at least half of the time in the 3 days before death.[14] Fortunately, a more recent study has demonstrated improved pain assessment and treatment in the ICU.[162]

OPIOID USE

Opioid use at the end of life is common, although consumption dramatically varies throughout the world.[19] In a 2012 study of 1068 patients at six U.S. medical centers, 70% of patients received an opioid in the last week of life, and 47% received opioids in the last 24 hours.[163] Some physicians are hesitant to use opioids at the end of life for fear of hastening a patient's death. A study by Morita in 2001 retrospectively analyzed opioid and sedative consumption of 209 patients in the 48 hours before death and found no difference in survival based on opiate or sedative dose.[164] A small study on the rate of increase of opioids found no correlation with time to death, although total morphine doses were relatively low overall in the study.[165] A larger study by Portenoy in 2006 showed a weak association with total opioid dose and time to death, but this association appeared to account for less than 10% of the variance even when combined with other variables.[166] Most experts believe that appropriately administered opioids do not hasten death, can be safely used, and generally do not require invoking the doctrine of double effect.[167] Some authors have urged caution with the use of opioids in patients with cancer and uncertain prognoses to decrease the risk of opioid dependence and abuse in patients with the possibility of a long life after treatment,[168] but overall, opioids should be titrated based on the clinician's assessment of the pain.

Interventional Pain Management at the End of Life

Despite the guidance provided by the WHO Stepladder,[168a] 10% to 20% of cancer patients have pain that is refractory to parenteral management.[168b,c] Select patients may benefit from interventional pain modalities.[156a] However, patients at the end of life may be more prone to bleeding from coagulopathy or thrombocytopenia and infection from immunosuppression. These issues need to be evaluated carefully by an interventional pain specialist. Abdominal pain, especially for pancreatic cancer, can be treated with celiac plexus blocks or neurolysis, while pelvic pain may be addressed with superior hypogastric blocks or neurolysis. These techniques are described in detail in Chapter 51. Less invasive modalities such as peripheral nerve blocks or trigger point injections may also be beneficial.

Neuraxial (i.e., intrathecal and epidural) analgesia can decrease numerical pain scores while significantly decreasing oral opioid intake, which may lead to fewer side effects such as constipation and sedation.[139a] In a randomized controlled trial of 202 patients with refractory cancer pain comparing comprehensive medical management versus an implantable intrathecal drug delivery system, those in the intrathecal group had significant reductions in fatigue and depressed level of consciousness. Additionally, this study showed a trend toward improved survival, with 53.9% of patients receiving intrathecal analgesia remaining alive at 6 months compared with 37.2% of the control group ($P = .06$).[168d]

NAUSEA AND VOMITING

Nausea and vomiting are common complaints in the palliative care and hospice populations and cause significant distress for patients and families.[169] Many techniques and medications used in the treatment of nausea and vomiting are similar to those used in the perioperative period. As with every patient, the first step in treating nausea and vomiting is a thorough evaluation of possible causes (Fig. 52.12). The following section highlights issues specific to patients with life-limiting diseases.

Nausea and Vomiting Related to Chemotherapy and Radiation Therapy

Many patients undergoing chemotherapy experience anticipatory nausea and vomiting. The 2011 American Society of Clinical Oncology Practice Guidelines for chemotherapy and radiation therapy include the prescription of a 5-hydroxytryptamine-3 antagonist, such as ondansetron, often with dexamethasone, and the addition of a neurokinin-1 antagonist, such as aprepitant, for the most emetogenic chemotherapy regimens.[170] Benzodiazepines may also be beneficial. For nonchemotherapy-related or radiation therapy-related nausea and vomiting, no Level 1a or 1b evidence is currently available to guide decisions on the choice of an antiemetic agent in the palliative care population. Unlike routine postoperative nausea and vomiting, patients may benefit from scheduled antiemetics with additional medications as needed.

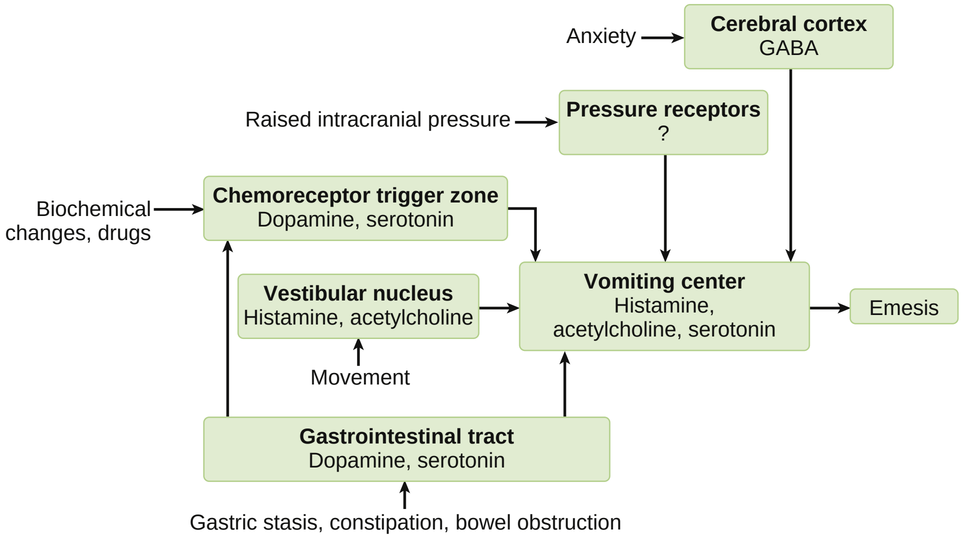

Fig. 52.12 Causes of nausea and vomiting. *GABA,* Gamma-aminobutyric acid. (From Gupta M, Davis M, LeGrand S, et al. Nausea and vomiting in advanced cancer: the Cleveland Clinic protocol. *J Support Oncol.* 2013;11:8–13.)

BOWEL OBSTRUCTION

Some patients with abdominal tumors may develop partial or complete bowel obstruction. First-line therapy consists of medical management, often with steroids and octreotide.[171] Surgical outcomes for patients with bowel obstruction and a life expectancy of less than 2 months are poor,[172] and gastrointestinal stents should be considered. Placement of a nasogastric tube should be considered for immediate relief while other options are considered. A venting gastrostomy tube is an option in patients who are refractory to treatment and can allow the patients to enjoy the taste of food while allowing gastric decompression.

ARTIFICIAL HYDRATION AND NUTRITION

Many patients receiving palliative care are unable to take in food or fluids because of nausea, dysphagia, or obstruction. The decision of whether to administer artificial hydration and nutrition is often a difficult one for patients and physicians. Both parties may hold strong cultural or religious views, and many describe a fear of "starving" the patient.[173] Symptoms of hunger are less common in advanced disease, and thirst can be treated with ice chips or mouth swabs.[174] The administration of artificial hydration and nutrition is associated with risks of fluid overload leading to choking or edema, as well as diarrhea and nausea.[175] Additional risks associated with a gastrostomy tube include dislodgement and the possible increased need for restraints.[175] The administration of enteral or parenteral nutrition and hydration is considered a medical intervention, and, as such, the risks and benefits should be discussed with patients and families.[173] The benefit of artificial hydration and nutrition has been established for patients in a persistent vegetative state or those with acute stroke or head injury, short-term critical illness, oropharyngeal cancers, and possibly bulbar amyotrophic lateral sclerosis.[176] Additionally, artificial hydration may improve symptoms of delirium in patients with cancer, although it does not influence survival in most advanced cancers.[177] The use of percutaneous feeding tubes in patients with advanced dementia does not prevent pneumonia or improve survival and is not recommended.[178,179] For some patients, a time-limited trial of artificial hydration or nutrition may be appropriate to evaluate for benefit, such as improvement in delirium, while monitoring for side effects.

DYSPNEA

Dyspnea is "a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity,"[180] as differentiated from breathing that appears labored or fast to an observer. Dyspnea is common in patients with a high risk of death[182,183] and was identified as the most distressing symptom by patients who could self-report in the ICU, regardless of their mechanical ventilation status.[184] Dyspnea increases closer to the time of death, even in patients without known cardiopulmonary disease.[185] Treatment is either aimed at reversing the cause of dyspnea (e.g., thoracentesis for an effusion) or at symptom management. Nonpharmacologic therapy such as a fan or pulmonary rehabilitation may be helpful.[186] Studies of low-dose opioids in patients with refractory dyspnea support their safety and efficacy.[187,188] A randomized, double-blind, crossover study of 48 COPD patients who were taking 20 mg of sustained-release morphine daily showed a significant improvement in dyspnea with minimal side effects.[189] Studies of the effect of benzodiazepines with and without opioids for dyspnea are small and mixed, with a trend toward possible benefit.[190-192]

DEPRESSION AND ANXIETY IN THE PATIENT RECEIVING PALLIATIVE CARE

Depression and anxiety are common at the end of life, with estimates ranging from 5% to 30% and 7% to 13%, respectively.[198] Many factors contribute to psychological distress, including social, economic, spiritual, and

TABLE 52.4 Distinguishing Characteristics of Grief and Depression in Patients Who Are Terminally Ill

Characteristic	Normal Grief	Depression
Nature of response	Adaptive	Maladaptive
Focus of distress	In response to a particular loss; not affecting all aspects of life	Pervasive; affecting all aspects of life
Symptom fluctuations	Symptoms coming in waves, generally improving with time	Constant
Mood	Sadness and dysphoria	Protracted and constant depression or flat affect
Interests and capacity for pleasure	Interests and capacity for pleasure remaining intact; diminishing engagement in activities because of functional decline	Anhedonia with significant diminished interest or pleasure in all activities
Hope	Episodic and focal loss of hope; hopes possibly changing over time; giving positive orientation toward the future	Persistent and pervasive hopelessness
Self-worth	Maintaining self-worth, although with feelings of helplessness	Worthlessness with the belief that one's life has no value
Guilt	Regrets and guilt over specific events	Excessive feelings of guilt
Suicidal ideation	Passive and fleeting desire for a hastened death	Preoccupation with a desire to die

From Widera EW, Block SD. Managing grief and depression at the end of life. *Am Fam Physician.* 2012;86:259–264.

physical stressors associated with serious illness.[199] A rapid screening test for depression consisting of two questions, "Are you depressed?" and "Have you experienced a loss of interest in things or activities you would normally enjoy?" has a sensitivity of 91% and a specificity of 68% and has been validated in the palliative care population.[200] Patients who screen positive for depression or who have suicidal or homicidal ideations should be referred to a psychiatrist or other experienced provider. Depression should be distinguished from delirium and normal grief (Table 52.4).[201] For the anesthesiologist, recognizing depression and making appropriate referrals is important.

Treatments for depression vary by life expectancy. Selective serotonin reuptake inhibitors and monoamine oxidase inhibitors may be appropriate for patients with a longer life expectancy, since the time to onset is 1 to 2 months. For patients with a life expectancy of weeks to a few months, methylphenidate has been well studied in the cancer population. The onset of action is 1 to 3 days and is generally effective and well-tolerated for depression and fatigue.[202,203]

DELIRIUM AT THE END OF LIFE

Delirium is covered in depth in Chapter 65. It affects 28% to 88% of patients who are terminally ill, with increasing incidence as death approaches.[204,205] The Confusion Assessment Method has been validated in the palliative care population.[206,207] Some patients may have more than one possible cause of delirium (Box 52.6). Delirium can have a major impact on a patient's ability to make a well-informed decision about treatment options, including surgery, which may have ethical and legal implications. Most patients who recover remember being delirious, and those who do find it very distressing.[208]

As much as half of the delirium near the end of life may be reversible.[205] Increased likelihood of reversible delirium is associated with a younger age, less severe impairment, and lack of organ failure.[209] Patients with true terminal delirium have a very short life expectancy.[204] Attempts at workup should be based on the patient's goals of care (Box 52.7). For example, the family of a cancer patient

BOX 52.7 **Evaluation of Delirium**

Determining the goals of care
Reviewing medications
Considering the possibility of withdrawal
Identifying any hematologic or metabolic abnormalities or organ failure
  Complete metabolic panel
  Complete blood count
Evaluating oxygen levels
  Oxygen saturation
Identifying infections
  Urine culture
  Blood cultures
  Chest x-ray imaging
Performing specialized testing, if appropriate
  Electroencephalogram
  Arterial blood gas
  Tests for disseminated intravascular coagulation
  Test for thyroid-stimulating hormone
  Computed tomography scan or magnetic resonance imaging scan of the brain
  Lumbar puncture

From LeGrand SB. Delirium in palliative medicine: a review. *J Pain Symptom Manage.* 2012;44:583–594.

who develops delirium but previously had an acceptable quality of life may desire a workup for potential reversible causes (e.g., urinalysis, chest x-ray study, or brain imaging), whereas the family of a patient who had previously been nearly comatose and expected to die in hours to days may not want to subject their family member to further workup.

Although delirium is often associated with agitation, hypoactive delirium, during which a patient may have decreased interaction with the environment and exhibit inattention, is likely more common than most clinicians appreciate.[210] Hypoactive delirium is considered disturbing by patients who experience it, but no consensus has been reached on whether or how to treat hypoactive delirium.[211]

While delirium is treated similarly for palliative care patients as it is for medical and surgical inpatients, there is inadequate evidence for specific recommendations on management of delirium in the palliative care settings.[211a] Conventional and atypical antipsychotics can both be used to treat delirium in palliative care.[211a] Some patients may ultimately require palliative sedation to treat terminal delirium.

BLEEDING IN THE PATIENT RECEIVING PALLIATIVE CARE

Bleeding can be caused by numerous pathologic conditions, including coagulation disorders and cancers. Fibrinolytic inhibitors such as tranexamic acid, interventional radiologic procedures such as embolization, and surgery have been suggested for patients with compatible goals and life expectancy.[212] Exsanguination in patients receiving palliative care is uncommon but can be upsetting to patients, families, and providers. No randomized trials of best treatments have been conducted. Some practical suggestions include the use of dark towels, suction, holding pressure, and staying with the patient. Medications such as benzodiazepines, opioids, and ketamine are frequently suggested during exsanguination to provide sedation and amnesia.[213]

The Dying Process

Most physicians have observed people die but may not have witnessed the dying process. Over 500,000 people die in the ICU every year in the United States alone, and more die after an ICU stay.[213a] Understanding the dying process is important because family members may ask physicians what the dying process will be like for the patient. Anesthesiologists need to be able to recognize the signs that a patient is imminently dying.

The variation in the timing with which a patient develops many symptoms is substantial, with 84% of patients being drowsy or comatose 24 hours before death, and acrocyanosis and the loss of a radial pulse occurring a median of 1 hour before death[213b] (Table 52.5). Some of the most noticeable symptoms will be cessation of oral intake, lack of responsiveness, and a build-up of oral and tracheal secretions leading to gurgling, sometimes called the “death rattle.” Terminal secretions are thought be from the airway or oropharynx that cannot be cleared because of the inability to cough or swallow.[213c] Despite widespread clinical use of antimuscarinic drugs for terminal secretions, strikingly few studies support this practice. A large study comparing atropine, hyoscine butylbromide, and scopolamine showed improvement in symptoms but no difference among those agents.[213d] A study using sublingual atropine versus placebo showed no difference.[213e] Of note, many of these small studies have multiple methodologic limitations. Family members differ in their interpretations of the sound, with some but not all finding it unsettling.[213f] Many clinicians believe the noisy breathing is not bothersome to patients because most are generally unconscious, although evidence to support this view is lacking.

WITHDRAWAL OF LIFE SUPPORT

Some patients or family members may wish to discontinue mechanical ventilation or other forms of life support. Withdrawal of life support is ethically acceptable and respects patient autonomy. Anesthesiologists can provide expertise in the management of pain and anxiety with the withdrawal of ventilation. Multiple protocols using an opioid for pain or dyspnea and a benzodiazepine for agitation or anxiety are available in the ICU for withdrawal of ventilatory support.[213g] Interestingly, studies of protocolized life support withdrawal have not demonstrated an improvement in provider perception of the quality of death.[213h,i] A pilot study evaluating the effect of the use of a protocol to guide withdrawal of life support suggested that while symptoms are generally well-controlled around the time of extubation, areas in need of improvement include documentation of family meetings and provision of emotional or spiritual support to families and staff members.[213j] This study highlights the need to devote specific attention to the nonsymptomatic needs of patients and families near the time of death, including making arrangements for rituals and family support, and involving a spiritual advisor for some families.[213g]

TABLE 52.5 Changes During the Dying Process

Changes	Exhibited Signs
Fatigue, weakness	Decreasing function Decreasing attention to hygiene Inability to move around the bed Inability to lift head off the pillow
Cutaneous ischemia	Erythema over bony prominences Skin breakdown Wounds
Pain	Facial grimacing Tension in forehead and between eyebrows
Decreasing food intake, wasting	Anorexia Poor intake Aspiration, asphyxiation Weight loss, muscle, and fat loss notable in temples
Loss of ability to close eyes	Eyelids not closed Whites of eyes show (with or without pupils visible)
Decreasing fluid intake, dehydration	Poor intake Aspiration Peripheral edema attributable to hypoalbuminemia Dehydration, dry mucous membranes or conjunctivae
Cardiac dysfunction, renal failure	Tachycardia Hypertension followed by hypotension Peripheral cooling Peripheral and central cyanosis (bluing of extremities) Mottling of the skin (livedo reticularis) Venous pooling along dependent skin surfaces Dark urine Oliguria, anuria
Neurologic dysfunction, including: Decreased level of consciousness	Increased drowsiness Difficulty awakening Nonresponsive to verbal or tactile stimuli
Decreased ability to communicate	Difficulty finding words Monosyllabic words, short sentences Delayed or inappropriate responses Not verbally responsive
Respiratory dysfunction	Change in ventilatory rate—increasing first, then slowing Decreasing tidal volume Abnormal breathing patterns—apnea, Cheyne-Stokes respirations, agonal breaths Loss of ability to swallow Dysphagia Coughing, choking Loss of gag reflex Buildup of oral and tracheal secretions Gurgling
Loss of sphincter control	Incontinence of urine or bowels Maceration of skin Perineal candidiasis Terminal delirium Early signs of cognitive failure, (e.g., day-night reversal) Agitation, restlessness Purposeless, repetitious movements Moaning, groaning
Rare, unexpected events	Bursts of energy just before death occurs, the "golden glow" Aspiration, asphyxiation

From Ferris FD. Last hours of living. *Clin Geriatr Med.* 2004;20:641–667, vi.

Outcomes of Withdrawal of Life Support

One study of 74 medical patients in an ICU who were expected to die shortly after extubation showed a mean morphine dose of 5.3 mg/h in the last hour of mechanical ventilation, followed by 10.6 mg/h during the hour before death.[213k] The average time to death was 153 minutes after extubation, with a range of 4 to 934 minutes. Somewhat surprisingly, each 1 mg/h increase of morphine corresponded to an 8-minute delay in death.[213k] This response is similar to an earlier study that showed a 13-minute increase in the time to death with each 1 mg/h increase of benzodiazepine.[213l] Longer time interval between initiation of withdrawal of life support to death has been associated with improved family satisfaction.[213m]

Paralytic Drugs in the Withdrawal of Life Support

As noted in Chapter 8, patients should not be paralyzed before extubation of the trachea; it obscures symptom assessment and may lead to patient suffering. Patients already on paralytic medications should await the return of neuromuscular function before extubation unless doing so causes undue burden on the patient.[213n]

PEDIATRIC HOSPICE CARE AND PALLIATIVE CARE

Palliative care is appropriate for many children with chronic serious illnesses, and the WHO states that pediatric palliative care can be successfully delivered even in resource-limited settings.[1] Pediatric hospice and palliative care are similar to their adult counterparts, but the patient's developmental stage is incorporated into the pediatric care plan. Explanations of illness and death depend on the child's developmental stage. A child younger than 2 years of age has no concept of death, whereas a 10-year-old child may be interested in the details of the dying process.[213o]

Characteristics of the Pediatric Palliative Care Population

The variety of diagnoses for patients in pediatric palliative care are wider than those for adults[213p] with the most common disorders being congenital and neuromuscular in origin.[213p] In the largest observational study to date, over one third of pediatric patients referred for palliative care consultation services were 1 to 9 years of age, one third were 10 to 18 years old, and less than 20% were younger than 1 year of age.[213p] Children often have prolonged survival after the initial palliative care consultation compared to adults.[213p] Some disorders, including chromosomal or severe developmental abnormalities, are rarely seen by adult palliative care physicians. The decision to forgo treatment with curative intent is generally difficult for families, and prognostication is similarly difficult for providers.[213o] Moreover, multiple legal issues related to declining medical treatment in children exist that differ from those related to adults.[213q]

Symptom Management in Pediatric Palliative Care

Historically, symptoms in children with serious illnesses have been poorly managed. In a retrospective survey of parents of deceased children, parents noted that their children suffered "a lot" or "a great deal," mostly from pain, fatigue, and dyspnea.[213q] In contrast to most studies of adults near the end of life, a 2011 study noted neurologic symptoms being more prevalent, [213p] suggesting a need for a better understanding and treatment of these symptoms in the pediatric population. Regional anesthesia has been reported as being of benefit to pediatric patients with pain that is difficult to manage with systemic treatment.[213r] Data on specific therapies for children are limited, and many practitioners use medications based on adult studies.

53 Anesthesia for Thoracic Surgery

PETER SLINGER and JAVIER H. CAMPOS

KEY POINTS

- Patients undergoing pulmonary resection should have a preoperative assessment of their respiratory function in three areas: lung mechanical function, pulmonary parenchymal function, and cardiopulmonary reserve (the "three-legged stool" of respiratory assessment).
- Patients with underlying lung disease have a decreased risk of respiratory complications when pulmonary resections are performed with video-assisted thoracoscopic surgery (VATS)
- After lung resection surgery, it is usually possible to wean and extubate patients with adequate predicted postoperative respiratory function in the operating room provided they are "AWaC" (alert, warm, and comfortable).
- Interventions that have been shown to decrease the incidence of respiratory complications in high-risk patients undergoing thoracic surgery include cessation of smoking, physiotherapy, and thoracic epidural analgesia.
- Geriatric patients are at high risk for cardiac complications, particularly cardiac arrhythmias (see Chapter 65), after large pulmonary resections. Preoperative exercise capacity is the best predictor of postthoracotomy outcome in the older patient.
- The ability to perform fiberoptic bronchoscopy and a detailed knowledge of bronchial anatomy are necessary for anesthesiologists to provide reliable lung isolation.
- Use of double-lumen endobronchial tubes (DLTs) is the standard method of providing lung isolation in adults. Bronchial blockers are a reasonable alternative for lung isolation in patients with abnormal upper or lower airways.
- With the use of intravenous anesthetic techniques or volatile anesthetics at less than or equal to 1–minimum alveolar concentration (MAC) doses, hypoxemia during one-lung ventilation (OLV) occurs infrequently. The use of continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) as treatment for hypoxemia during OLV should be guided by the individual patient's lung mechanics.
- The use of large tidal volumes during OLV (e.g., 10 mL/kg) can contribute to acute lung injury, particularly in patients at increased respiratory risk, such as after pneumonectomy.
- The underlying principle of management of a patient with a bronchopleural fistula is to secure lung isolation before positive pressure ventilation repositioning the patient for surgery.
- Anesthetic management of a patient with an anterior or superior mediastinal mass should be guided by the patient's symptoms, the preoperative computed tomography (CT) scan, and the echocardiography findings. The fundamental principle of anesthetic management for these patients is *noli ponti ignii consumere* ("don't burn your bridges").
- Continuous paravertebral local anesthetic blockade combined with multimodal analgesia is a reasonable alternative to epidural analgesia for thoracic surgery with fewer side effects.

Introduction

Thoracic anesthesia encompasses a wide variety of diagnostic and therapeutic procedures involving the lungs, airways, and other intrathoracic structures. As the patient population presenting for noncardiac thoracic surgery has evolved so have the anesthetic techniques to manage these patients. Thoracic surgery at the beginning of the last century was primarily for infectious indications (lung abscess, bronchiectasis, empyema). Although these cases still present for surgery in the postantibiotic era, now the most common indications are related to malignancies (pulmonary, esophageal, and mediastinal). In addition, the last two decades have seen the beginnings of surgical therapy for end-stage lung diseases with procedures such as lung transplantation and lung volume reduction. Fundamental to anesthetic management for the majority of thoracic procedures are two techniques: (1) lung isolation to facilitate surgical access within the thorax, and (2) management of one-lung anesthesia. In this chapter, we initially discuss preanesthetic assessment for thoracic surgery, outline intraoperative management principles common to most thoracic surgical procedures, discuss specific anesthetic considerations in common and less common surgical operations, and we finish with a description of postoperative management issues in thoracic surgical patients.

PREOPERATIVE EVALUATION OF THE THORACIC SURGERY PATIENT (SEE CHAPTER 31)

Preoperative anesthetic assessment prior to chest surgery is a continually evolving science and art. Recent advances in anesthetic management, surgical techniques, and perioperative care have expanded the envelope of patients now considered to be "operable."[1] This discussion focuses primarily on preanesthetic assessment for pulmonary resection surgery in cancer patients. However, the basic principles described will apply to all other types of nonmalignant pulmonary resections and to other chest surgery.

Although 87% of patients with lung cancer will die of their disease, the 13% cure rate represents approximately 26,000 survivors per year in North America. Surgical resection is responsible for essentially all of these cures. A patient with a "resectable" lung cancer has a disease that is still local or local-regional in scope and can be encompassed in a plausible surgical procedure. An "operable" patient is someone who can tolerate the proposed resection with acceptable risk.

The patient is commonly assessed initially as an outpatient and often not by the member of the anesthesia staff who will actually administer the anesthesia. The actual contact with the responsible anesthesiologist may be only 10 to 15 minutes prior to induction. It is necessary to organize and standardize the approach to preoperative evaluation for these patients into two temporally disjoint phases: the initial (clinic) assessment and the final (day-of-admission) assessment. Elements vital to each assessment are described.

An increasing number of thoracic surgeons are now being trained to perform "lung-sparing" resections such as sleeve-lobectomies or segmentectomies, and resections with minimally invasive techniques such as video-assisted thoracoscopic surgery (VATS) or robotic surgery. The postoperative preservation of respiratory function has been shown to be proportional to the amount of functioning lung parenchyma preserved. To assess patients with limited pulmonary function the anesthesiologist must appreciate these newer surgical options in addition to the conventional open lobectomy or pneumonectomy.

It is the anesthesiologist's responsibility to use the preoperative assessment to identify patients at elevated risk and then to use that risk assessment to stratify perioperative management and focus resources on the high-risk patients to improve their outcome. This is the primary function of the preanesthetic assessment. However, there are occasions when the anesthesiologist should contribute his or her opinion about whether a specific high-risk patient will tolerate a specific surgical procedure. This may occur preoperatively but also occurs intraoperatively when the surgical findings suggest that a planned procedure, such as a lobectomy, may require a larger resection, such as a pneumonectomy. For these reasons, it is imperative that the anesthesiologist have a complete preoperative knowledge of the patient's medical status and also an appreciation of the pathophysiology of lung resection surgery. Prethoracotomy assessment naturally involves all of the factors of a complete anesthetic assessment: past history, allergies, medications, upper airway, and so on. This section concentrates on the additional information, beyond a standard anesthetic assessment, that the anesthesiologist needs to manage a patient undergoing a pulmonary resection.

PERIOPERATIVE COMPLICATIONS

The major cause of perioperative morbidity and mortality in the thoracic surgical population is respiratory complications. Major respiratory complications—atelectasis, pneumonia, and respiratory failure—occur in 15% to 20% of patients and account for the majority of the expected 3% to 4% mortality.[2] For other types of surgery, cardiac and vascular complications are the leading cause of early perioperative morbidity and mortality. Cardiac complications such as arrhythmia and ischemia occur in 10% to 15% of the thoracic population.

ASSESSMENT OF RESPIRATORY FUNCTION

The best assessment of respiratory function comes from a detailed history of the patient's quality of life. All patients undergoing a pulmonary resection should have baseline simple spirometry done preoperatively.[3] Objective measures of pulmonary function are required to guide anesthetic management and to have this information in a format that can be easily transmitted between members of the health care team. Respiratory function can be divided into three related but somewhat independent areas: respiratory mechanics, gas exchange, and cardiopulmonary interaction (i.e., exercise capacity). The basic functional units of extracellular respiration are to move the oxygen: (1) into the alveoli, (2) into the blood, and (3) into the tissues (the process is reversed for carbon dioxide removal).

RESPIRATORY MECHANICS

Many tests of respiratory mechanics and volumes show correlation with postthoracotomy outcome: forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), maximal voluntary ventilation (MVV), residual volume/total lung capacity ratio (RV/TLC), and so on (see Chapter 13 on pulmonary function testing). It is useful to express these as a percent of predicted volumes corrected for age, sex, and height (e.g., FEV_1 %). Of these, the most valid single test for postthoracotomy respiratory complications is the predicted postoperative FEV_1 (ppoFEV_1 %),[4] which is calculated as:

$$\text{ppoFEV}_1\ \% = \text{preoperative FEV1}\ \% \times (1 - \%\ \text{functional lung tissue removed}/100).$$

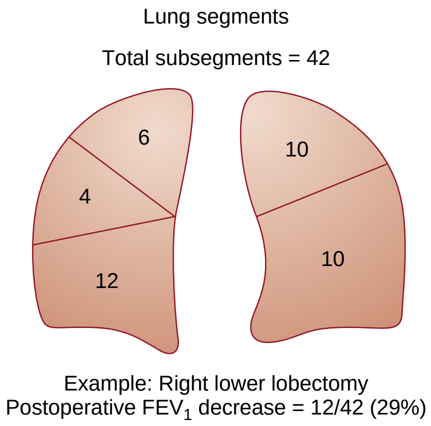
One method of estimating the percent of functional lung tissue is based on a calculation of the number of functioning subsegments of the lung removed (Fig. 53.1). Patients with a ppoFEV_1 greater than 40% are at low risk for postresection respiratory complications. The risk of major respiratory complications is increased in the subgroup with ppoFEV_1 less than 40% (although not all patients in this subgroup develop respiratory complications) and patients with ppoFEV_1 less than 30% are at high risk.

Lung Parenchymal Function

As important to the process of respiration as the mechanical delivery of air to the distal airways is the subsequent ability of the lung to exchange oxygen and carbon dioxide between the pulmonary vascular bed and the alveoli. Traditionally arterial blood gas data such as PaO_2 less than 60 mm Hg or $PaCO_2$ greater than 45 mm Hg have been used as cut-off values for pulmonary resection. Cancer resections have now been successfully done or even combined with volume reduction in patients who do not meet these criteria, although they remain useful as warning indicators of increased risk. The most useful test of the gas exchange capacity of the lung is the diffusing capacity for carbon monoxide (DLCO). The DLCO correlates with the total functioning surface area of alveolar-capillary interface. The corrected DLCO can be used to calculate a postresection (predicted postoperative [ppo]) value using the same calculation as for the FEV_1 (see Fig. 53.1). A ppoDLCO less than 40% correlates with both increased respiratory and cardiac complications and is, to a large degree, independent of the FEV_1.[5] The DLCO, but not the FEV_1, is negatively affected by preoperative chemotherapy and may be the most important predictor of complications in this subgroup of patients. Some authors feel a higher cutoff risk-threshold for ppoDLCO of less than 50% may be more appropriate.[6] The National Emphysema Treatment Trial has shown that patients with a preoperative FEV_1 or DLCO less than 20% had an unacceptably high perioperative mortality rate.[7] These can be considered as the absolute minimal values compatible with a successful outcome.

Cardiopulmonary Interaction

The final and perhaps most important assessment of respiratory function is an assessment of the cardiopulmonary interaction (evaluation of the patient's exercise capacity). Exercise capacity is commonly described in units of metabolic equivalent of task (MET). Sitting quietly requires an oxygen consumption of 3.5 mL/kg /min (1 MET). Climbing one flight of stairs is 4 METs. In a patient who is a reliable historian, the ability to climb two flights of stairs without stopping is a minimum to be considered for pulmonary resection evaluation. While there is no absolute definition of the height of a flight of stairs, 10 feet (3 M) is a commonly used standard. Patients who cannot give a reliable history, or are limited in their ability to climb stairs because of comorbidities, will require simple and/or formal exercise testing.



Lung segments
Total subsegments = 42
6
4
12
10
10
Example: Right lower lobectomy
Postoperative FEV_1 decrease = 12/42 (29%)

Fig. 53.1 The number of subsegments of each lobe are used to calculate the predicted postoperative (ppo) pulmonary function (e.g., after a right lower lobectomy, a patient with a preoperative *FEV_1* [or DLCO] 70% of normal would be expected to have a $ppoFEV_1$ of 70% × (1 − 29/100) = 50%. *ppoDLCO*, Predicted postoperative diffusing capacity for carbon monoxide; *$ppoFEV_1$*, predicted postoperative forced expiratory volume. (Reproduced with permission from Slinger P. *Principles and Practice of Anesthesia for Thoracic Surgery*. New York: Springer; 2011.)

The most valid simple exercise test is the maximal distance that a patient can walk in 6 minutes.[8] The 6-minute walk test (6MWT) shows an excellent correlation with maximal oxygen consumption (VO_2max) and requires no laboratory equipment. It has been shown in COPD patients that the VO_2max can be estimated from the 6MWT distance in meters divided by 30 (i.e., 6MWT of 450 m: estimated VO_2max = 450/30 = 15 mL/kg/min).[9] Other simple exercise tests include shuttle walking in which a patient walks at a fixed, and gradually increased, rate between 2 markers 10 meters apart. A distance of less 250 meters correlates with a VO_2max of less than 10 mL/kg/min.[3] Another simple test is exercise-oximetry: patients with a decrease of blood oxygen saturation (SpO_2) greater than 4% during exercise are at increased risk.

Formal laboratory exercise testing is the "gold standard" for assessment of cardiopulmonary function[10] and the VO_2max is the most useful predictor of postthoracotomy outcome. The risk of morbidity and mortality is high if the preoperative VO_2max is less than 15 mL/kg/min, and very high if less than 10 mL/kg/min (35% predicted).[11] Few patients with a VO_2max greater than 20 mL/kg/min (75% predicted) have respiratory complications. (For comparison, a VO_2max of 85 mL/kg/min was documented for the American cyclist Lance Armstrong in 2005[12]; since then several elite rowers and cross-country skiers have exceeded this.)

After pulmonary resection, right ventricular dysfunction appears to be in proportion to the amount of functioning pulmonary vascular bed removed. The exact etiology and duration of this dysfunction remain unknown. Clinical evidence of this hemodynamic problem is minimal when the patient is at rest but is dramatic when the patient exercises, leading to elevation of pulmonary vascular pressures, limitation of cardiac output, and absence of the normal decrease in pulmonary vascular resistance (PVR) usually seen with exertion.[13]

Ventilation Perfusion Scintigraphy

Prediction of postresection pulmonary function can be further refined by assessment of the preoperative contribution of the lung or lobe to be resected using ventilation-perfusion (V/Q) lung scanning. If the lung region to be resected is nonfunctioning or minimally functioning, the prediction of postoperative function can be modified accordingly. This is particularly useful in pneumonectomy patients and V/Q scanning should be considered for any pneumonectomy patient who has a preoperative FEV_1 and/or DLCO less than 80%. However, V/Q scanning is of limited usefulness to predict postlobectomy function.[14]

Combination of Tests

No single test of respiratory function has shown adequate validity as a sole preoperative assessment. Prior to surgery, an estimate of respiratory function in all three areas—lung mechanics, parenchymal function, and cardiopulmonary interaction—should be made for each patient. These three aspects of pulmonary function form the "three-legged stool" that is the foundation of prethoracotomy respiratory assessment (Box 53.1).

An algorithm for preoperative respiratory evaluation of the patient for pulmonary resection is presented in Fig. 53.2. The recent increased use of minimally invasive surgical techniques has had a major impact on the assessment of operability in lung cancer patients. Patients previously considered high risk for thoracotomy may not be high risk if the procedure can be done with VATS or robotic surgery.[15] The threshold for increased risk in ppoFEV$_1$ for lobectomy appears to have shifted from less than 40% for open thoracotomy to less than 30% for VATS (Fig. 53.3).[16] The same shift may also have occurred for ppoDLCO (Fig. 53.4).[17]

If a patient has a ppoFEV$_1$ greater than 40%, the trachea usually can be extubated in the operating room at the conclusion of surgery assuming the patient is alert, warm, and comfortable ("AWaC"). If the ppoFEV$_1$ is greater than 30% and exercise tolerance and lung parenchymal function exceed the increased-risk thresholds, then tracheal extubation can be done in the operating room depending on the status of associated medical conditions. Patients in this subgroup who do not meet the minimal criteria for cardiopulmonary and parenchymal function should be considered for staged weaning from mechanical ventilation postoperatively. Patients with a ppoFEV$_1$ of 20% to 30% and favorable predicted cardiorespiratory and parenchymal function can be considered for early tracheal extubation if thoracic epidural analgesia is used or if the resection is performed with VATS. In the increased-risk group, the presence of several associated factors and diseases should be documented during the preoperative assessment and will enter into the consideration for postoperative management (discussed later).

BOX 53.1 The Three-Legged Stool of Prethoracotomy Respiratory Assessment

Respiratory mechanical function. Most valid test: ppoFEV$_1$. Threshold for increased risk : <30%–40% (see text)
Lung parenchymal function. Most valid test: ppoDLCO. Threshold for increased risk: <30%–40% (see text)
Cardiopulmonary interaction. Most valid test: Maximal oxygen consumption. Threshold for increased risk: <15 mL/kg/min

ppoDLCO, Predicted postoperative diffusing capacity for carbon monoxide; *ppoFEV$_1$*, predicted postoperative forced expiratory volume.

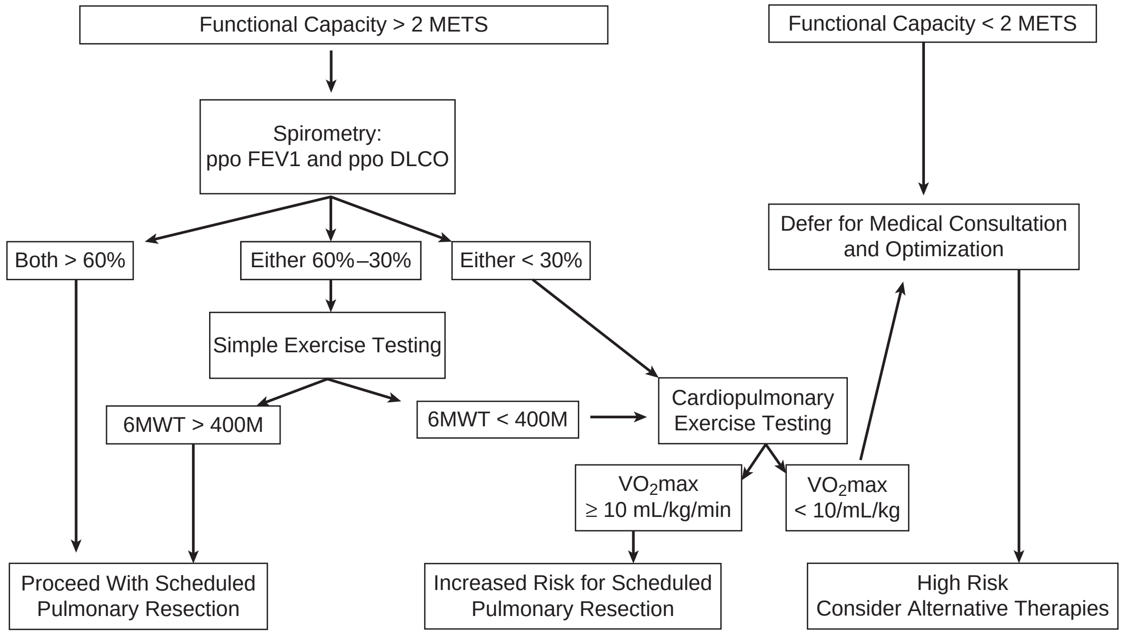
Concomitant Medical Conditions

CARDIAC DISEASE

Cardiac complications are the second most common cause of perioperative morbidity and mortality in the thoracic surgical population.

Ischemia

Because the majority of pulmonary resection patients have a smoking history, they already have one risk factor for coronary artery disease. Elective pulmonary resection surgery is regarded as an "intermediate-risk" procedure in terms of perioperative cardiac ischemia.[18] The overall documented incidence of postthoracotomy ischemia is 5% and peaks on days 2 to 3 postoperatively. Beyond the standard history, physical, and electrocardiogram, routine screening testing for cardiac disease does not appear to be cost-effective for



Functional Capacity > 2 METS
Functional Capacity < 2 METS
Spirometry:
ppo FEV1 and ppo DLCO
Both > 60%
Either 60%–30%
Either < 30%
Defer for Medical Consultation and Optimization
Simple Exercise Testing
6MWT > 400M
6MWT < 400M
Cardiopulmonary Exercise Testing
VO2max ≥ 10 mL/kg/min
VO2max < 10/mL/kg
Proceed With Scheduled Pulmonary Resection
Increased Risk for Scheduled Pulmonary Resection
High Risk
Consider Alternative Therapies

Fig. 53.2 A flow-diagram for preoperative respiratory investigation of a patient for pulmonary resection surgery. *MET*, Metabolic equivalent of task; *ppoDLCO*, predicted postoperative diffusing capacity for carbon monoxide; *ppoFEV$_1$*, predicted postoperative forced expiratory volume in 1 second; *6MWT*, = 6-minute walk test distance in meters. (Based on data from Brunelli A, Kim A, et al. Physiological evaluation of the patient with lung cancer being considered for resectional surgery. *Chest.* 2013;143:e166s–190s; and Licker M, Triponez F, Diaper J, et al. Preoperative evaluation of lung cancer patients. *Curr Anesthesiol Rep.* 2014;4:124–134.)

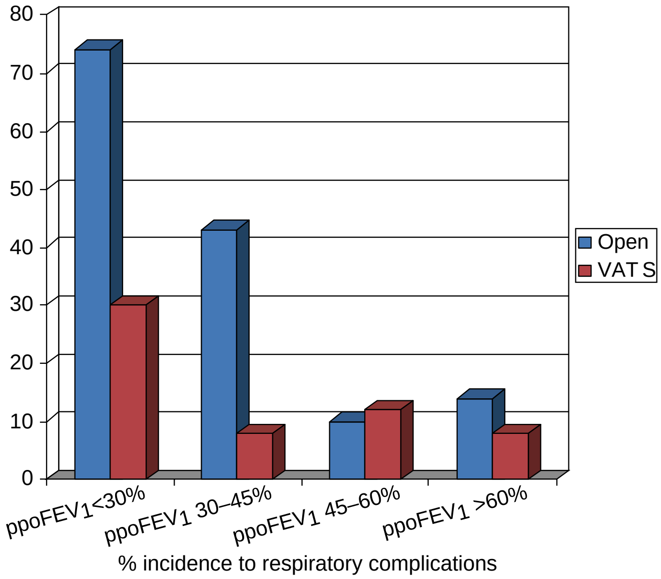


Fig. 53.3 A comparison of the incidence of postoperative respiratory complications after open thoracotomy versus *VATS* lobectomies for lung cancer. *FEV_1*, forced expiratory volume in one second; *ppo*, Predicted postoperative value; *VATS*, video-assisted thoracoscopic surgery. This was a nonrandomized retrospective study. It appears that the threshold for increased risk may have decreased from <40% ppoFEV$_1$ in the open group to <30% in the VATS group. (Based on data from Berry M, et al. *Ann Thorac Surg*. 2010;89:1044–1052.)

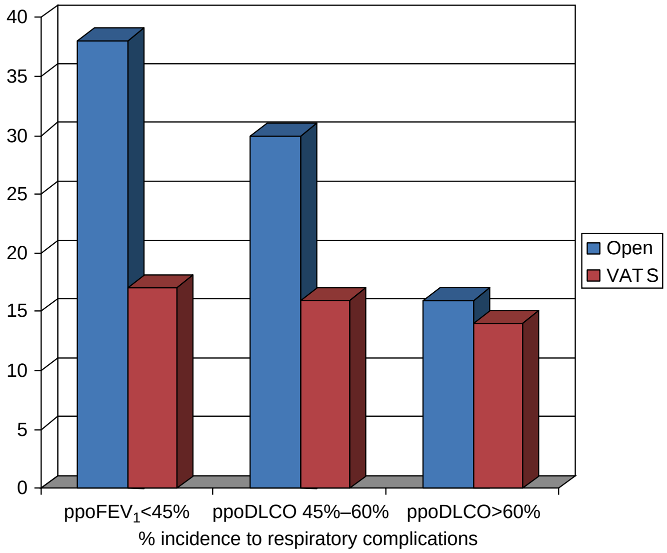

Fig. 53.4 A comparison of the incidence of postoperative respiratory complications after open thoracotomy versus VATS lobectomies for lung cancer. *DLCO*, diffusing capacity for carbon monoxide; *ppo*, Predicted postoperative value; *VATS*, video-assisted thoracoscopic surgery. It appears there is a threshold for increased risk in open procedures with less than 60% ppoDLCO. A threshold for VATS procedures could not be clearly identified, however there were very few patients with a ppoDLCO <40% in this study. (Based on data from Berry M, et al. *Ann Thorac Surg*. 2010;89:1044–1052.)

all prethoracotomy patients. Noninvasive testing is indicated in patients with major (i.e., unstable ischemia, recent infarction, severe valvular disease, significant arrhythmia) or intermediate (i.e., stable angina, remote infarction, previous congestive failure, diabetes) clinical predictors of myocardial risk. Therapeutic options to be considered in patients with significant coronary artery disease are optimization of medical therapy, coronary angioplasty, or coronary artery bypass, either before or at the time of lung resection. Timing of lung resection surgery after a myocardial infarction is always a difficult decision to make. Limiting the delay to 4 to 6 weeks in a medically stable and fully investigated and optimized patient seems acceptable after myocardial infarction. The appropriate delay after coronary stenting is conventionally 4 to 6 weeks after bare metal stents and 6 months after drug-eluting stents.[19,20] Surgery should be delayed until it is safe to temporarily discontinue major antiplatelet drugs (except aspirin).[20] Preoperative investigation of the patient with coronary artery disease for pulmonary resection should follow the most recent guidelines of the American College of Cardiology (see Chapter 31).[21]

Arrhythmia

Dysrhythmias are a common complication of pulmonary resection surgery and the incidence is 30% to 50% of patients in the first week postoperatively, when Holter monitoring is used.[22] Of these arrhythmias, 60% to 70% are atrial fibrillation. Several factors correlate with an increased incidence of arrhythmias, including extent of lung resection (pneumonectomy, 60%; vs. lobectomy, 40%; vs. nonresection thoracotomy, 30%), intrapericardial dissection, intraoperative blood loss, and age of the patient. Extrapleural pneumonectomy patients are a particularly high-risk group.[23]

Two factors in the early postthoracotomy period interact to produce atrial arrhythmias: 1. increased flow resistance through the pulmonary vascular bed because of permanent (lung resection) or transient (atelectasis, hypoxemia) causes, with attendant strain on the right side of the heart; and 2. increased sympathetic stimuli and oxygen requirements, which are maximal on the second postoperative day as patients become more mobile.

In some patients undergoing a pneumonectomy, the right heart may not be able to increase its output adequately to meet the usual postoperative stress. Transthoracic echocardiographic studies have shown that pneumonectomy patients develop an increase in right ventricular systolic pressure as measured by the tricuspid regurgitation jet (TRJ) on postoperative day 2 but not on day 1. An increase in TRJ velocity has been associated with postthoracotomy supraventricular tachyarrhythmias.[24] Preoperative exercise testing, which assesses the cardiopulmonary interaction, can predict postthoracotomy arrhythmias. Patients with COPD are more resistant to pharmacologic-induced heart rate control when they develop postthoracotomy atrial fibrillation and often require multiple drugs.[25]

Guidelines for the prevention of atrial fibrillation after thoracic surgery written by the American Association of Thoracic Surgeons are presented in Table 53.1.[26] At present, diltiazem is the most useful drug for postthoracotomy arrhythmia prophylaxis.[19] It seems that atrial arrhythmias are a sign of the dysfunctional right heart and preventing the complication does not solve the underlying problem. β-Adrenergic blockers may be the most effective drug to prevent arrhythmias, but there are concerns about their routine use in patients with reactive airways diseases.[27]

TABLE 53.1 Recommendations for Prevention of Postoperative Atrial Fibrillation (AF) in Thoracic Surgery

All Patients	High Risk for AF
	Includes: Anterior mediastinal mass, lobectomy, pneumonectomy, and esophagectomy
Continue β-blockers if taken preoperatively	Diltiazem, if preserved cardiac function and not taking β-blockers
Magnesium if serum level is low or suspected total body stores depleted	Consider amiodarone
	Consider statins

BOX 53.2 Modified Classification of Pulmonary Hypertension for Anesthesia

Left Heart Disease	Lung Disease
Systolic dysfunction	Pulmonary vascular disease
Diastolic dysfunction	Chronic lung diseases, hypoxemia, sleep apnea
Mitral valvular disease: stenosis, regurgitation	Thromboembolic pulmonary hypertension
Congenital cardiac disease	Miscellaneous: Autoimmune, metabolic, etc.

Congestive Heart Failure

During one-lung ventilation (OLV) for thoracotomy or thoracoscopy there is an obligate 20% to 30% shunt through the nonventilated lung. If the baseline cardiac output is decreased, the fall in mixed venous oxygen saturation (SvO_2) will lead to an exaggerated fall in arterial oxygen saturation. Patients with a history of congestive heart failure and/or cardiomyopathy may tolerate OLV poorly. They will need monitoring of venous saturation and inotropes to support cardiac output.

Pulmonary Hypertension

Patients with degrees of pulmonary hypertension (mean pulmonary arterial pressure [PAP] > 25 mm Hg by catheterization or systolic PAP > 35)[28] may present for a variety of noncardiac thoracic surgical procedures including pulmonary resections for malignant or benign lesions, esophageal surgery, or vascular surgery.[29] Compared to patients with normal pulmonary pressures, patients with pulmonary hypertension are particularly at increased risk of respiratory complications and the need for prolonged intubation after noncardiac surgery.[30] There are five different major diagnostic groups in the classification of pulmonary hypertension, with multiple subgroups of each group.[31] However, for the anesthesiologist, there are two main types of pulmonary hypertension: pulmonary hypertension due to left heart disease and pulmonary hypertension due to lung disease (Box 53.2). Most of the anesthesia literature has focused on patients with underlying cardiac disease.[32] However, patients who present for noncardiac surgery are more likely to have pulmonary hypertension secondary to lung disease.[33] The prevalence of pulmonary hypertension in severe chronic lung disease ranges from 40% to 50%.[34]

The myocardium of the right ventricle is normally perfused throughout the cardiac cycle. The increased right ventricular transmural and intracavitary pressures associated with pulmonary hypertension may restrict perfusion of the right coronary artery during systole, especially as PAPs approach systemic levels. Avoiding hypotension is key to managing these patients. In practice, this can be a challenge to achieve because anesthetics are commonly associated with a decrease in systemic vascular resistance (SVR) (e.g., propofol and inhalation anesthetics) and a variable effect on PVR. Ketamine or etomidate are useful anesthetic induction drugs in pulmonary hypertension due to lung disease.[35] Inotropes and inodilators such as dobutamine and milrinone may improve hemodynamics in patients with pulmonary hypertension secondary to left heart disease. However, they can decrease systemic vascular tone and tachycardia, and can cause a deterioration in the hemodynamics of patients with pulmonary hypertension due to lung disease. To maintain a systemic arterial blood pressure that is greater than the pulmonary pressure, vasopressors such as phenylephrine or norepinephrine are commonly used.[36] Vasopressin is also useful to maintain systemic pressures. Vasopressin appears to significantly increase systolic blood pressure without affecting PAP in patients with pulmonary hypertension (Fig. 53.5).[37,38] In patients with severe pulmonary hypertension, selective inhaled pulmonary vasodilators including nitric oxide (NO; 10–40 ppm)[39] or nebulized prostaglandins (prostacyclin 50 ng/kg/min) (Fig. 53.6)[40] should be considered (Box 53.3).

At present, the basis of intraoperative monitoring for a patient with pulmonary hypertension having noncardiac thoracic surgery remains the pulmonary artery catheter. However, pulmonary artery data alone can be misleading in these patients. Rising pulmonary artery pressures are almost always a bad sign. Falling pulmonary artery pressures may be a good sign, indicating pulmonary vasodilation, or may be a very bad sign indicating impending right ventricular decompensation. Thus pulmonary artery pressure data need to be followed in concert with cardiac output or mixed venous saturation data. Transesophageal echocardiography (TEE) is also helpful to monitor right heart function during thoracic surgery. Advances in echocardiography technology may make continuous objective monitoring of right ventricle function more possible in the near future.[41]

Although there have been multiple case reports of the successful use of lumbar epidural analgesia and anesthesia in obstetric patients with pulmonary hypertension,[42] there are very few reports of the use of thoracic epidural analgesia in pulmonary hypertension. Patients with pulmonary hypertension due to lung disease seem to be extremely dependent on tonic cardiac sympathetic innervation for normal hemodynamic stability. Animal studies suggest that the hemodynamic response to an increase in right ventricular afterload is very different with thoracic versus lumbar epidurals. In one study, right ventricle contractility increased as afterload increased in animals with lumbar epidural local anesthetic blockade, similar to the response in animals without neuraxial block. The cardiac sympathectomy of thoracic epidural blockade abolished this increase in contractility (Fig. 53.7).[43] Because of the increased risk of postoperative respiratory complications in these patients,

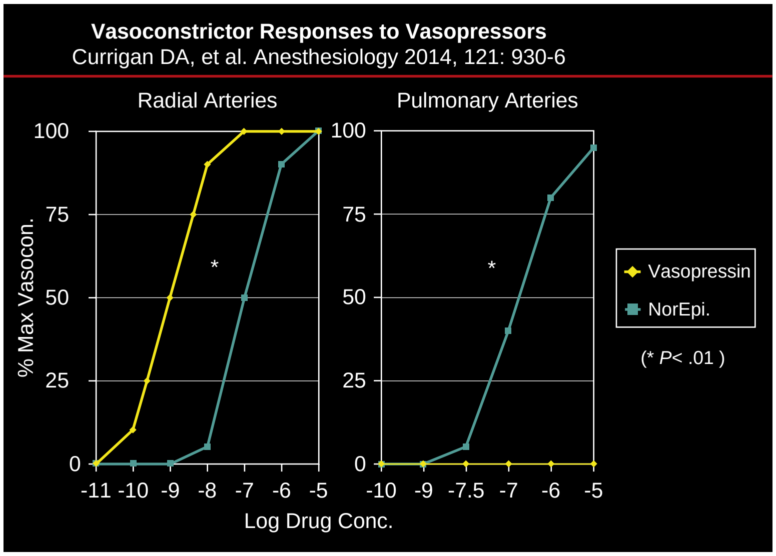

Fig. 53.5 In vitro maximal vasoconstriction (Max Vasocon.) dose-response curves of human radial arteries *(left)* and pulmonary arteries *(right)* to vasopressin and norepinephrine (NorEpi). All vasoconstrictors studied (including phenylephrine and metaraminol) showed similar dose-response patterns in both types of arteries except vasopressin, which showed no constriction of pulmonary arteries. (Based on data from: Currigan DA, Hughes RJA, Wright CE, et al. Vasoconstrictor responses to vasopressor agents in human pulmonary and radial arteries. *Anesthesiology*. 2014;121:930–936.)

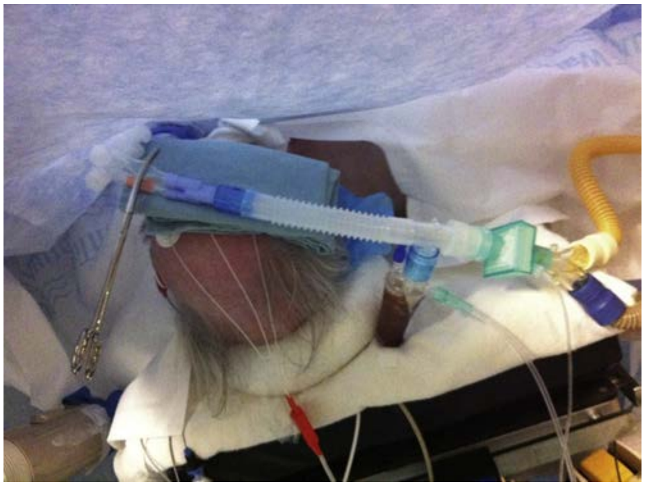

Fig. 53.6 Prostacyclin can be delivered continuously into a standard anesthetic circuit and the dose titrated as needed. In the photograph prostacyclin is delivered by nebulization to the ventilated lung via a double-lumen tube during thoracic surgery and one-lung ventilation in a patient with pulmonary hypertension.

BOX 53.3 Management Principles for Pulmonary Hypertension Secondary to Lung Disease

1. Avoid hypotensive and vasodilating anesthetic agents whenever possible
2. Ketamine does not exacerbate pulmonary hypertension
3. Support mean systolic pressure with vasopressors: norepinephrine, phenylephrine, vasopressin
4. Use inhaled pulmonary vasodilators (nitric oxide, prostacyclin) in preference to intravenous vasodilators when necessary
5. Use thoracic epidural local anesthetics cautiously and with inotropes when necessary
6. Monitor cardiac output

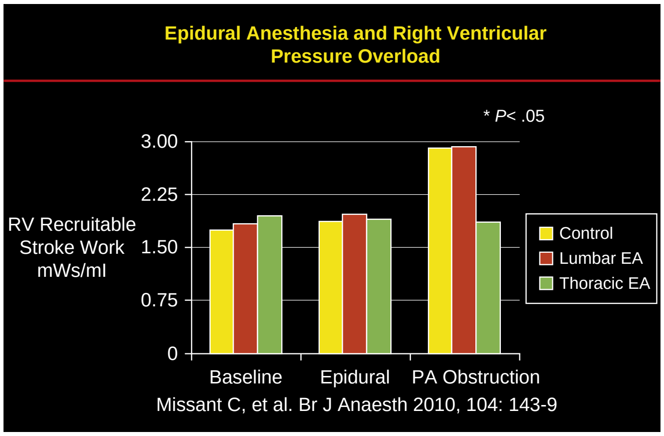

Fig. 53.7 Right ventricular *(RV)* recruitable stroke work, a measure of *RV* contractility, measured in three groups of anesthetized pigs: *Control*, no epidural group; *Lumbar EA*, lumbar epidural group; *Thoracic EA*, thoracic epidural group. Epidural bupivacaine injection had no effect on RV function in any of the study groups. Subsequent inflation of a balloon in the main pulmonary artery (PA Obstruction), increased RV afterload and resulted in a compensatory increase in RV contractility in the Control and Lumbar EA groups but not in the Thoracic EA group. (Based on data from Missant C, Claus P, Rex S, Wouters PF. Differential effects of lumbar and thoracic epidural anaesthesia on the haemodynamic response to acute right ventricular pressure overload. *Br J Anaesth*. 2009;104:143–149.)

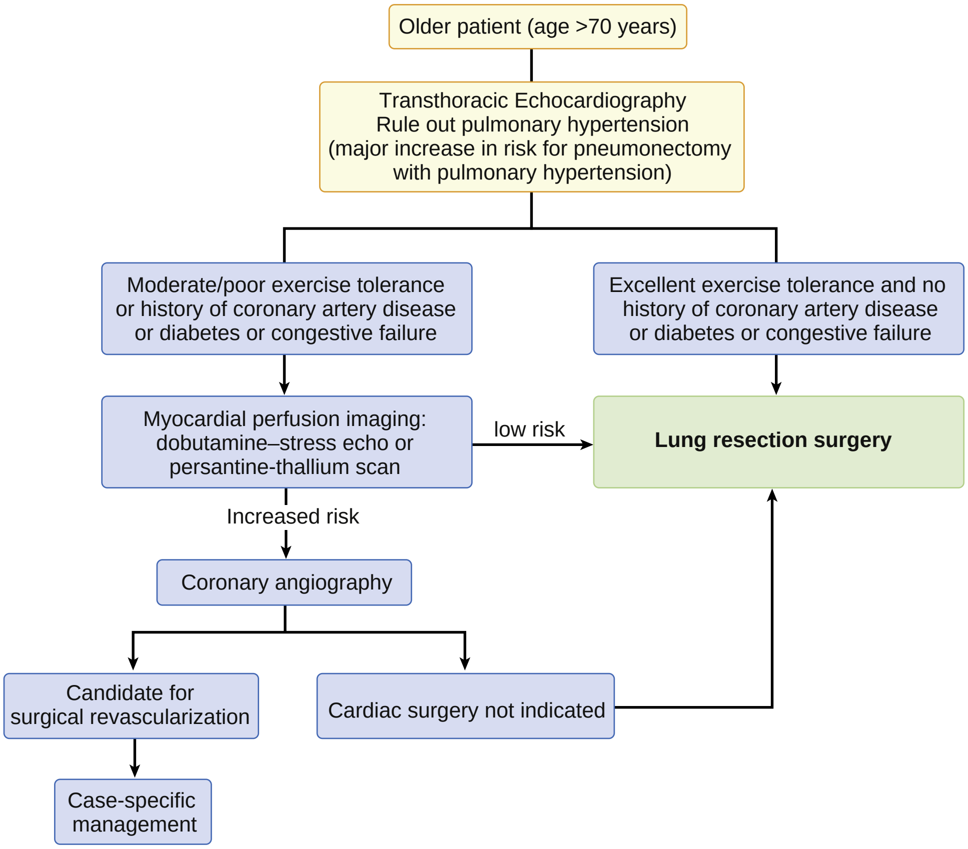
the use of postoperative thoracic epidural analgesia is often desirable. However, these patients often require a low-dose infusion of inotropes or vasopressors during thoracic epidural local analgesia, which may necessitate continued central venous catheterization and intensive care unit admission. Paravertebral analgesia has been associated with better postthoracotomy hemodynamic stability versus thoracic epidural analgesia in patients with normal cardiac function[44] but this has not been specifically studied in pulmonary hypertensive patients.



Older patient (age >70 years)
Transthoracic Echocardiography
Rule out pulmonary hypertension
(major increase in risk for pneumonectomy with pulmonary hypertension)
Moderate/poor exercise tolerance or history of coronary artery disease or diabetes or congestive failure
Excellent exercise tolerance and no history of coronary artery disease or diabetes or congestive failure
Myocardial perfusion imaging: dobutamine–stress echo or persantine-thallium scan
low risk
Lung resection surgery
Increased risk
Coronary angiography
Candidate for surgical revascularization
Cardiac surgery not indicated
Case-specific management

Fig. 53.8 Algorithm for the preoperative cardiac assessment of older patients for thoracic (noncardiac) surgery.

AGE

There is no maximum age that is a cutoff for pulmonary resection.[4] The operative mortality in a group of patients 80 to 92 years of age was 3%, a very respectable figure, in one series.[45] However, the rate of respiratory complications (40%) was double that expected in a younger population, and the rate of cardiac complications (40%), particularly arrhythmias, was nearly triple that which would be seen in younger patients. In older patients, thoracotomy should be considered a high-risk procedure for cardiac complications, and cardiopulmonary function is the most important part of the preoperative assessment. An algorithm for the cardiac assessment of the elderly for thoracic surgery is presented in Fig. 53.8. Although the mortality resulting from lobectomy among the older patients is acceptable, the mortality from pneumonectomy, particularly right pneumonectomy, is excessive.[46] Quality of life after pneumonectomy is significantly worse than after lesser pulmonary resections.[47] For these reasons, lung-sparing pulmonary resections are performed whenever possible. As a proportion of all lung cancer resections, pneumonectomy has decreased to approximately one third of its share of 15 years ago.[48] Exercise tolerance seems to be the primary determinant of outcome in older patients. Older patients should have, as a minimum cardiac investigation, a transthoracic echocardiogram to rule out pulmonary hypertension.

RENAL DYSFUNCTION

Renal dysfunction following pulmonary resection surgery was previously associated with a high mortality. Golledge and Goldstraw[49] reported a perioperative mortality of 19% (6/31) in patients in whom a significant elevation of serum creatinine developed in the postthoracotomy period, compared with 0% (0/99) in those who did not show any renal dysfunction. More recently, postthoracotomy renal dysfunction has not been found to be associated with increased mortality.[50] Predictive factors for renal dysfunction include preoperative hypertension, angiotensin II receptor blockers, use of hydroxyethyl starch, and open thoracotomies.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The most common concurrent illness in the thoracic surgical population is COPD, which incorporates three disorders: emphysema, peripheral airways disease, and chronic bronchitis. Any individual patient may have one or all of these conditions, but the dominant clinical feature is impairment of expiratory airflow.[51] Assessment of the severity of COPD is made on the basis of the FEV_1% of predicted values. The American Thoracic Society categorizes stage I as greater than 50% predicted, stage II as 35% to 50%, and stage III as less than 35%. Stage I patients should not have significant dyspnea, hypoxemia, or hypercarbia, and other causes should be considered if these are present.

Respiratory Drive

Many patients with stage II or III COPD have an elevated $PaCO_2$ at rest. It is not possible to differentiate these "CO_2-retainers" from nonretainers on the basis of history, physical examination, or spirometric pulmonary function testing.[52] CO_2 retention is related more to an inability to maintain the increased work of respiration (W_{resp}) required to keep the $PaCO_2$ normal in patients with mechanically inefficient pulmonary function and not primarily resulting from an alteration of respiratory control mechanisms. It was previously thought that chronically hypoxemic/hypercapnic patients relied on a hypoxic stimulus for ventilatory drive and became insensitive to $PaCO_2$. This explained the clinical observation that COPD patients in incipient respiratory failure could be put into a hypercapnic coma by the administration of a high concentration of oxygen (fraction of inspired oxygen [FiO_2]). In actuality, only a minor fraction of the increase in $PaCO_2$ in such patients is caused by a diminished respiratory drive, because minute ventilation is basically unchanged.[53] The $PaCO_2$ rises because a high FiO_2 causes a relative decrease in alveolar ventilation and an increase in alveolar dead space and shunt by the redistribution of perfusion away from lung areas of relatively normal V/Q matching to areas of very low V/Q ratio because regional hypoxic pulmonary vasoconstriction (HPV) is decreased[54] and also as a result of the Haldane effect.[55] However, supplemental oxygen must be administered to these patients postoperatively to prevent the hypoxemia associated with the unavoidable fall in functional residual capacity (FRC). The attendant rise in $PaCO_2$ should be anticipated and monitored. To identify these patients preoperatively, all stage II and III COPD patients need an arterial blood gas analysis.

Nocturnal Hypoxemia

COPD patients desaturate more frequently and severely than normal patients during sleep.[56] This is due to the rapid/shallow breathing pattern that occurs in all patients during REM sleep. In COPD patients breathing air, this causes a significant increase in the respiratory dead space/tidal volume (V_D/V_T) ratio and a fall in alveolar oxygen tension (PAO_2) and PaO_2. This is not the sleep-apnea-hypoventilation syndrome (SAHS). There is no increased incidence of SAHS in COPD.

Right Ventricular Dysfunction

Right ventricular dysfunction occurs in as many as 50% of COPD patients. The dysfunctional right ventricle is poorly tolerant of sudden increases in afterload[57] such as the change from spontaneous to controlled ventilation.[58] Right ventricular function becomes critical in maintaining cardiac output as the pulmonary artery pressure rises. The RV ejection fraction does not increase with exercise in COPD patients as it does in normal patients. Chronic recurrent hypoxemia is the cause of the RV dysfunction and the subsequent progression to cor pulmonale. Patients who have episodic hypoxemia in spite of normal lungs (e.g., central alveolar hypoventilation, SAHS)[59] develop the same secondary cardiac problems as COPD patients. The only therapy that improves long-term survival and decreases right-sided heart strain in COPD is administration of increasing concentrations of oxygen. COPD patients who have a resting PaO_2 less than 55 mm Hg, as well as those who have decreases to less than 44 mm Hg with exercise, should receive supplemental oxygen at home. The goal of supplemental oxygen is to maintain a PaO_2 60 to 65 mm Hg. Compared with patients with chronic bronchitis, emphysematous COPD patients tend to have a decreased cardiac output and mixed venous oxygen tension while maintaining lower pulmonary artery pressures.

Bullae

Many patients with moderate or severe COPD will develop cystic air spaces in the lung parenchyma known as bullae. These bullae will often be asymptomatic unless they occupy more than 50% of the hemithorax, in which case the patient will present with findings of restrictive respiratory disease in addition to their obstructive disease. A bulla is a localized area of loss of structural support tissue in the lung with elastic recoil of surrounding parenchyma (Fig. 53.9). The pressure in a bulla is actually the mean pressure in the surrounding alveoli averaged over the respiratory cycle. This means that during normal spontaneous ventilation the intrabulla pressure is actually slightly negative in comparison to the surrounding parenchyma.[60] However, whenever positive-pressure ventilation is used the pressure in a bulla will become positive in relation to the adjacent lung tissue and the bulla will expand with the attendant risk of rupture, tension pneumothorax, and bronchopleural fistula. Positive-pressure ventilation can be used safely in patients with bullae provided the airway pressures are kept low and there is adequate expertise and equipment immediately available to insert a chest drain and obtain lung isolation if necessary. Management of patients for bullectomy is discussed later.

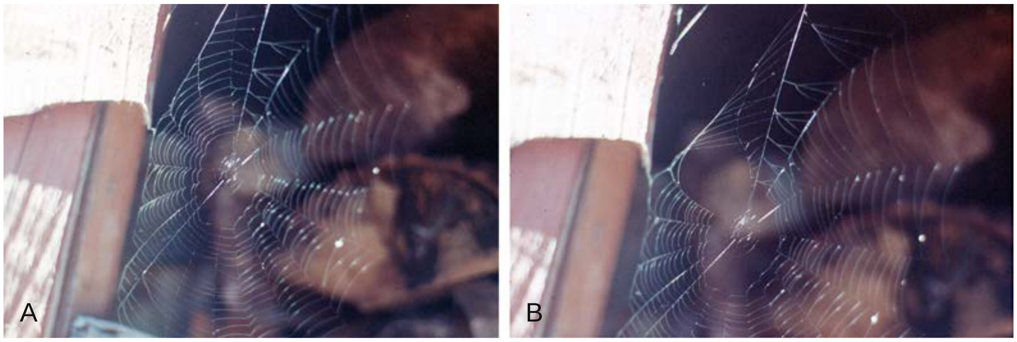


Fig. 53.9 (A) A spider's web as a lung model to demonstrate the pathophysiology of bullae. (B) Breaking one septum of the spider's web causes a bulla to appear as elastic recoil pulls the web away from the area where structural support has been lost. Although the cells surrounding the bulla appear compressed, this is only because of redistribution of elastic forces. It is not positive pressure inside the bulla that causes this appearance of surrounding compression. (Reproduced with permission from Slinger P. *Principles and Practice of Anesthesia for Thoracic Surgery*. New York: Springer; 2011.)

Flow limitation

Severe COPD patients are often "flow-limited" even during tidal volume expiration at rest.[61] Flow limitation is present in normal patients only during a forced expiratory maneuver. Flow limitation occurs when an equal pressure point (EPP) develops in the intrathoracic airways during expiration. During quiet expiration in the normal patient the pressure in the lumen of the airways always exceeds the intrapleural pressure because of the upstream elastic recoil pressure which is transmitted from the alveoli. The effect of this elastic recoil pressure diminishes as air flows downstream in the airway. With a forced expiration the intrapleural pressure may equal the intraluminal pressure at a certain point, the EPP, which then limits the expiratory flow. Then, any increase in expiratory effort will not produce an increase in flow at that given lung volume.[62]

Flow limitation occurs particularly in emphysematous patients, who primarily have a problem with loss of lung elastic recoil and have marked dyspnea on exertion. Flow limitation causes dyspnea because of stimulation of mechanoreceptors in the muscles of respiration, thoracic cage, and in the airway distal to the EPP. Any increase in the work of respiration will lead to increased dyspnea. This variable mechanical compression of airways by over-inflated alveoli is the primary cause of the airflow obstruction in emphysema.

Severely flow-limited patients are at risk for hemodynamic collapse with the application of positive-pressure ventilation due to dynamic hyperinflation of the lungs. Even the modest positive airway pressures associated with manual ventilation with a bag/mask at induction can lead to hypotension since these patients have no increased resistance to inspiration but a marked obstruction of expiration. In some of these patients this has contributed to the "Lazarus" syndrome in which patients have recovered from a cardiac arrest only after resuscitation and positive-pressure ventilation were discontinued.[63]

Auto-Positive End-Expiratory Pressure

Patients with severe COPD often breathe in a pattern that interrupts expiration before the alveolar pressure has fallen to atmospheric pressure. This incomplete expiration is due to a combination of factors which include flow limitation, increased work of respiration, and increased airway resistance. This interruption leads to an elevation of the end-expiratory lung volume above the FRC. This positive end-expiratory pressure (PEEP) in the alveoli at rest has been termed auto-PEEP or intrinsic-PEEP. During spontaneous respiration the intrapleural pressure will have to be decreased to a level which counteracts auto-PEEP before inspiratory flow can begin. Thus COPD patients can have an increased inspiratory load added to their already increased expiratory load.

Auto-PEEP becomes even more important during mechanical ventilation. It is directly proportional to tidal volume and inversely proportional to expiratory time. The presence of auto-PEEP is not detected by the manometer of standard anesthesia ventilators. It can be measured by end-expiratory flow interruption, a feature available on most intensive care ventilators. Auto-PEEP has been found to develop in most COPD patients during one-lung anesthesia.[64]

PREOPERATIVE THERAPY OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

There are four treatable complications of COPD that must be actively sought and therapy begun at the time of the initial prethoracotomy assessment. These are: atelectasis, bronchospasm, respiratory tract infections, and pulmonary edema (Table 53.2). Atelectasis impairs local lung lymphocyte and macrophage function predisposing to infection. Pulmonary edema can be very difficult to diagnose by auscultation in the presence of COPD and may present very abnormal radiological distributions (e.g., unilateral, upper lobes). Bronchial hyperreactivity may be a symptom of congestive failure or may represent an exacerbation of reversible airways obstruction. All COPD patients should receive maximal bronchodilator therapy as guided by their symptoms. Only 20% to 25% of COPD patients will respond to corticosteroids. In a patient who is poorly controlled on sympathomimetic and anticholinergic bronchodilators, a trial of corticosteroids may be beneficial.

PHYSIOTHERAPY

Patients with COPD have fewer postoperative pulmonary complications when a perioperative program of intensive chest physiotherapy is initiated preoperatively.[65] Among the different modalities available (cough and deep breathing, incentive spirometry, PEEP, continuous positive airway pressure [CPAP]), there is no clearly proven superior method. Family members or nonphysiotherapy hospital staff can easily be trained to perform effective preoperative chest physiotherapy, and this should be arranged at the time of the initial preoperative assessment. Even in the most severe COPD patient, it is possible to improve exercise tolerance with a physiotherapy program. Little improvement is seen before 1 month. Among COPD patients, those with excessive sputum benefit the most from chest physiotherapy.

A comprehensive program of pulmonary rehabilitation involving physiotherapy, exercise, nutrition, and education can improve functional capacity for patients with severe COPD.[66] These programs are usually of several months duration and are generally not an option in resections for malignancy although for nonmalignant resections in severe COPD patients, rehabilitation should be considered. The benefits of short duration rehabilitation programs prior to malignancy resection have not been fully assessed.

Smoking: Pulmonary complications are decreased in thoracic surgical patients who cease smoking for more

TABLE 53.2 Concurrent Problems That Should Be Treated Prior to Anesthesia in Chronic Obstructive Pulmonary Disease Patients

Problem	Method of Diagnosis
Bronchospasm	Auscultation
Atelectasis	Chest radiograph
Infection	History, sputum analysis
Pulmonary edema	Auscultation, chest radiograph

than 4 weeks before surgery.[67] Carboxyhemoglobin concentrations decrease if smoking is stopped more than 12 hours.[68] It is extremely important for patients to avoid smoking postoperatively. Smoking leads to a prolonged period of tissue hypoxemia. Wound tissue oxygen tension correlates with wound healing and resistance to infection. There is no rebound increase in pulmonary complications if patients stop for shorter (<8 week) periods before surgery.[69] Intensive smoking-cessation interventions are the most successful.[70]

PRIMARY THORACIC TUMORS

The majority of patients presenting for major pulmonary surgery will have some type of malignancy. Because the different types of thoracic malignancies have varying implications for both surgery and anesthesia, it is important for the anesthesiologist to have some knowledge of the presentation and biology of these cancers. By far the most common tumor is lung cancer. There are over 200,000 new cases of lung cancer diagnosed per year in North America and more than 1.2 million in the world. Lung cancer is currently the leading cause of cancer deaths in both sexes in North America subsequent to the peak incidence of smoking in the period 1940 to 1970.[71]

Lung cancer is broadly divided into small-cell lung cancer (SCLC) and non–small-cell lung cancer (NSCLC), with about 75% to 80% of these tumors being NSCLC. Other less common and less aggressive tumors of the lung include the carcinoid tumors (typical and atypical) and adenoid cystic carcinoma. In comparison to lung cancer, primary pleural tumors are rare. They include the localized fibrous tumors of pleura (previously referred to as benign mesotheliomas) and malignant pleural mesothelioma (MPM). Asbestos exposure is implicated in up to 80% of MPM. A dose-response relationship is not always apparent and even brief exposures can lead to the disease. An exposure history is often difficult to obtain because the latent period before clinical manifestation of the tumor may be as long as 40 to 50 years.

Tobacco smoke is responsible for approximately 90% of all lung cancers and the epidemiology of lung cancer follows the epidemiology of cigarette smoking with approximately a 3-decade lag time.[72] Other environmental causes include asbestos and radon gas (a decay product of naturally occurring uranium) which act as co-carcinogens with tobacco smoke. For a pack-a-day cigarette smoker the lifetime risk of lung cancer is approximately 1 in 14. Assuming current mortality patterns continue, cancer will pass heart disease as the leading cause of death in North America in this decade.

Non–Small-Cell Lung Cancer

This pathologically heterogeneous group of tumors includes squamous cell, adenocarcinoma, and large-cell carcinoma. Overall 5-year survival with surgery approaches 40%. This seemingly low figure must be viewed in the light of an estimated 5-year survival without surgery of less than 10%. Although it is not always possible to be certain of the pathology of a given lung tumor preoperatively, many patients will have a known tissue diagnosis at the time of preanesthetic assessment on the basis of prior cytology, bronchoscopy, mediastinoscopy, or transthoracic needle aspiration. This is useful information for the anesthesiologist to obtain preoperatively. Specific anesthetic implications of the different types of lung cancer are listed in Table 53.3.

TABLE 53.3 Anesthetic Considerations for Different Types of Lung Cancer

Type	Considerations
Squamous cell	Central lesions (predominantly) Often with endobronchial tumor Mass effects: obstruction, cavitation Hypercalcemia
Adenocarcinoma	Peripheral lesions Extrapulmonary invasion common Most Pancoast tumors Growth hormone, corticotropin Hypertrophic osteoarthropathy
Large Cell	Large, cavitating peripheral tumors Similar to adenocarcinoma
Small Cell	Central lesions (predominantly) Surgery usually not indicated Paraneoplastic syndromes Lambert-Eaton syndrome Fast growth rate Early metastases
Carcinoid	Proximal, endobronchial Bronchial obstruction with distal pneumonia Highly vascular Benign (predominantly) No association with smoking 5 year survival >90% Carcinoid syndrome (rarely)

Squamous Cell Carcinoma

This subgroup of NSCLC is strongly linked to cigarette smoking. The tumors tend to grow to a large size and metastasize later than others. They tend to cause symptoms related to local effects of a large tumor mass with a dominant endobronchial component, such as cavitation, hemoptysis, obstructive pneumonia, superior vena cava syndrome, and involvement of mainstem bronchus, trachea, carina, and main pulmonary arteries. Hypercalcemia may be associated with this cell type due to elaboration of a parathyroid-like factor and not due to bone metastases.

Adenocarcinoma

Adenocarcinoma is currently the most common NSCLC in both sexes. These tumors tend to be peripheral and often metastasize early in their course, particularly to brain, bones, liver, and adrenals. They often invade extrapulmonary structures, including chest wall, diaphragm, and pericardium. Almost all Pancoast tumors are adenocarcinomas. A variety of paraneoplastic metabolic factors can be secreted by adenocarcinomas such as growth hormone and corticotropin. Hypertrophic pulmonary osteoarthropathy (HPOE) is particularly associated with adenocarcinoma.

Bronchioloalveolar carcinoma is a subtype of adenocarcinoma that is not related to cigarette smoking. In its early stages it lines the alveolar membrane with a thin layer of tumor cells without destroying the alveolar architecture. Because of its low potential to spread outside of the lungs, multifocal bronchioloalveolar carcinoma can be treated by lung transplantation.[73]

Large-Cell Undifferentiated Carcinoma

This is the least common of the NSCLCs. It tends to present as a large, often cavitating peripheral tumor. The rapid growth rate may lead to widespread metastases, similar to adenocarcinoma.

Small-Cell Lung Cancer

This tumor of neuroendocrine origin is considered metastatic on presentation and is usually regarded as a medical, not a surgical, disease. Surgery is only very rarely indicated. The staging system differs from NSCLC and is divided simply into limited stage and extensive stage. Treatment of limited stage SCLC with combination chemotherapy (etoposide/cisplatin or cyclophosphamide/doxorubicin/vincristine) gives objective response rates in over 80% of patients. In addition these patients typically receive aggressive radiotherapy to the primary lung tumor and prophylactic cranial irradiation. Despite this initial response, the tumor invariably recurs and is quite resistant to further treatment. The overall survival rate is no better than 10%. Extensive-stage disease is treated with chemotherapy and palliative radiation as needed.

SCLC is known to cause a variety of paraneoplastic syndromes due to the production of peptide hormones and antibodies. The most common of these is hyponatremia, usually as a result of an inappropriate production of antidiuretic hormone (syndrome of inappropriate antidiuretic hormone secretion). Cushing syndrome and hypercortisolism through ectopic production of adrenocorticotropic hormone are also commonly seen.

A rare neurologic paraneoplastic syndrome associated with small-cell lung tumors is the Lambert-Eaton (also called Eaton-Lambert) myasthenic syndrome due to impaired release of acetylcholine from nerve terminals. This typically presents as proximal lower limb weakness and fatigability that may temporarily improve with exercise. The diagnosis is confirmed by electromyography showing increasing amplitude of unusual action potentials with high-frequency stimulation. Similar to true myasthenia gravis patients, myasthenic syndrome patients are extremely sensitive to nondepolarizing muscle relaxants. However, they respond poorly to anticholinesterase reversal agents.[74] It is important to realize that there may be subclinical involvement of the diaphragm and muscles of respiration. Thoracic epidural analgesia has been used following thoracotomy in these patients without complication. These patients' neuromuscular function may improve following resection of the lung cancer.

Carcinoid Tumors

These are part of a continuum of neuroendocrine tumors that form a spectrum of diseases from SCLC as the most malignant to typical carcinoid as the most benign. Five-year survival following resection for typical carcinoid exceeds 90%. Systemic metastasis is rare, as is the carcinoid syndrome, which is caused by the ectopic synthesis of vasoactive mediators, and is usually seen with carcinoid tumors of gut origin that have metastasized to the liver. Atypical carcinoid tumors are more aggressive and may metastasize. Carcinoid tumors can precipitate an intraoperative hemodynamic crisis or coronary artery spasm even during bronchoscopic resection.[75] The anesthesiologist should be prepared to deal with severe hypotension that may not respond to the usual vasoconstrictors and will require the use of the specific antagonists octreotide or somatostatin.[76]

Pleural Tumors

Localized fibrous tumors of pleura are usually large, space occupying masses that are attached to visceral or parietal pleura. They can be either benign or malignant.

MPMs are strongly associated with exposure to asbestos fibers. Their incidence in Canada has almost doubled in the past 15 years. With the phasing out of asbestos-containing products and the long latent period between exposure and diagnosis, the peak incidence is not predicted for another 10 years. The tumor initially proliferates within the visceral and parietal pleura, typically forming a bloody effusion. Most patients present with shortness of breath or dyspnea on exertion from this pleural effusion. Thoracentesis often relieves the symptoms but rarely provides a diagnosis. Pleural biopsy by VATS is most efficient to secure a diagnosis and talc pleurodesis is performed during the same anesthetic to treat the effusion.

MPMs respond poorly to therapy and the median survival is less than 1 year. In patients with early disease, extrapleural pneumonectomy may be considered but it is difficult to know whether survival is improved. Recently, several groups have reported improved results with combinations of radiation, chemotherapy, and surgery. Extrapleural pneumonectomy is an extensive procedure that is rife with potential complications, both intraoperative and postoperative.[77] Blood loss from the denuded chest wall or major vascular structures is always a risk. Complications related to resection of the diaphragm and pericardium are additional risks to that of pneumonectomy.

ASSESSMENT OF THE PATIENT WITH LUNG CANCER

At the time of initial assessment, cancer patients should be assessed for the "4 Ms" associated with malignancy (Box 53.4): mass effects, metabolic abnormalities, metastases, and medications. The prior use of medications that can exacerbate oxygen-induced pulmonary toxicity, such as bleomycin, should be considered.[78] Bleomycin is not used to treat primary lung cancers, but patients presenting for excision of lung metastases from germ-cell tumors often have received prior bleomycin therapy. Although the association between previous bleomycin therapy and pulmonary toxicity from high inspired oxygen concentrations is well documented, none of the details of the association are understood (i.e., safe doses of oxygen or safe period after bleomycin exposure). The safest anesthetic management is to use the lowest FiO_2 consistent with patient safety and closely monitor oximetry in any patient who has received bleomycin. We have seen lung cancer patients who received preoperative chemotherapy with cisplatin and then developed an elevation of serum creatinine when they received NSAIDs postoperatively. For this

BOX 53.4 Anesthetic Considerations in Lung Cancer Patients (the “4 Ms”)

1. Mass effects: Obstructive pneumonia, lung abscess, SVC syndrome, tracheobronchial distortion, Pancoast syndrome, recurrent laryngeal nerve or phrenic nerve paresis, chest wall or mediastinal extension
2. Metabolic effects: Lambert-Eaton syndrome, hypercalcemia, hyponatremia, Cushing syndrome
3. Metastases: Particularly to brain, bone, liver, and adrenal
4. Medications: Chemotherapy agents, pulmonary toxicity (bleomycin, mitomycin), cardiac toxicity (doxorubicin), renal toxicity (cisplatin)

reason, we do not routinely administer NSAIDs to patients who have been treated recently with cisplatin.

POSTOPERATIVE ANALGESIA

The strategy for postoperative analgesia should be developed and discussed with the patient during the initial preoperative assessment; a discussion of postoperative analgesia is presented at the end of this chapter. Many techniques have been shown to be superior to the use of on-demand parenteral (intramuscular or intravenous) opioids alone in terms of pain control. These include the addition of neuraxial blockade, paravertebral blocks, and antiinflammatories to narcotic-based analgesia. However, only epidural techniques have been shown to consistently have the capability to decrease postthoracotomy respiratory complications in high-risk patients.[2] Continuous paravertebral blockade may offer comparable analgesia with a lower rate of block failure and fewer side effects.[79]

At the time of initial preanesthetic assessment, the risks and benefits of the various forms of postthoracotomy analgesia should be explained to the patient. Potential contraindications to specific methods of analgesia should be determined, such as coagulation problems, sepsis, or neurologic disorders. If the patient is to receive prophylactic anticoagulants and the use of epidural analgesia has been elected, appropriate timing of anticoagulant administration and neuraxial catheter placement need to be arranged. American Society of Regional Anesthesia and Pain Medicine (ASRA) guidelines suggest an interval of 2 to 4 hours before or 1 hour after catheter placement for prophylactic heparin administration.[80] Low-molecular-weight heparin (LMWH) recommendations and precautions are: (1) a minimal interval of 12 hours after low-dose LMWH and (2) 24 hours after higher-dose LMWH before catheter placement.

PREMEDICATION

We do not routinely order preoperative sedation or analgesia for pulmonary resection patients. Mild sedation such as an intravenous short-acting benzodiazepine is often given immediately prior to placement of invasive monitoring lines and catheters. In patients with copious secretions, an antisialagogue (e.g., glycopyrrolate) is useful to facilitate fiberoptic bronchoscopy for positioning of a double-lumen endobronchial tube (DLT) or bronchial blocker. To avoid an intramuscular injection, this can be given orally or intravenously immediately after placement of the intravenous catheter. It is a common practice to use short-term intravenous antibacterial prophylaxis such as a cephalosporin in thoracic surgical patients. If it is the local practice to administer these drugs before admission to the operating room, they will have to be ordered preoperatively. Consideration for those patients allergic to cephalosporins or penicillin should be made at the time of the initial preoperative visit.

BOX 53.5 Initial Preanesthetic Assessment for Thoracic Surgery

1. All patients: assess functional capacity, spirometry, discuss postoperative analgesia, discontinue smoking
2. Patients with $ppoFEV_1$ or DLCO < 60%: exercise test
3. Cancer patients: consider the 4 Ms: mass effects, metabolic effects, metastases, medications
4. COPD patients: arterial blood gas, physiotherapy, bronchodilators
5. Increased renal risk: measure creatinine and blood urea nitrogen levels

COPD, Chronic obstructive pulmonary disease; *ppoDLCO*, predicted postoperative diffusing capacity for carbon monoxide; *$ppoFEV_1$*, predicted postoperative forced expiratory volume.

BOX 53.6 Final Preanesthetic Assessment for Thoracic Surgery

1. Review initial assessment and test results
2. Assess difficulty of lung isolation: examine chest radiograph and computed tomographic scan
3. Assess risk of hypoxemia during one-lung ventilation

SUMMARY OF THE INITIAL PREOPERATIVE ASSESSMENT

The anesthetic considerations that should be addressed at the time of the initial preoperative assessment are summarized in Box 53.5. Patients need to be specifically assessed for risk factors associated with respiratory complications, which are the major cause of morbidity and mortality following thoracic surgery.

FINAL PREOPERATIVE ASSESSMENT

The final preoperative anesthetic assessment for the majority of thoracic surgical patients is carried out immediately before admission of the patient to the operating room. At this time, it is important to review the data from the initial prethoracotomy assessment and the results of tests ordered at that time. In addition, two other specific areas affecting thoracic anesthesia need to be assessed: (1) the potential for difficult lung isolation and (2) the risk of desaturation during OLV (Box 53.6).

Difficult Endobronchial Intubation

The most useful predictor of difficult endobronchial intubation is the chest imaging (Fig. 53.10).

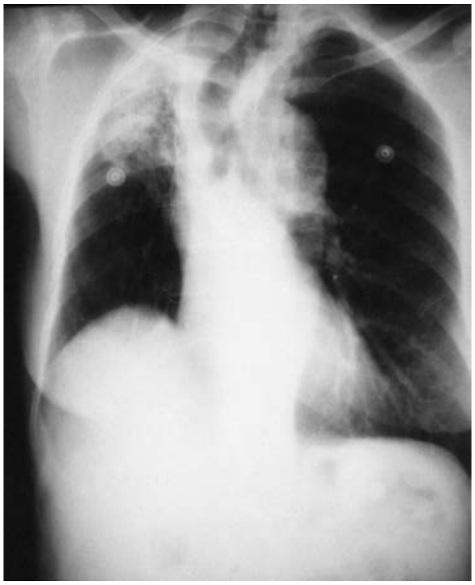

Fig. 53.10 Preoperative chest radiograph of a 50-year-old woman with a history of previous tuberculosis, right upper lobectomy, and recent hemoptysis presenting for right thoracotomy possible completion pneumonectomy. The potential problems positioning a left-sided double-lumen tube in this patient are easily appreciated by viewing the radiograph but are not mentioned in the radiologist's report. The anesthesiologist must solely examine the chest imaging preoperatively to anticipate problems in lung isolation. (Reproduced with permission from Slinger P. *Principles and Practice of Anesthesia for Thoracic Surgery*. New York: Springer; 2011.)

The anesthesiologist should view the chest imaging before induction of anesthesia because neither the radiologist's nor the surgeon's report of the imaging is made with the specific consideration of lung isolation in mind. Distal airway problems not detectable on the plain chest film can sometimes be visualized on the computed tomography (CT) scan: a side-to-side compression of the distal trachea, the so-called "saber-sheath" trachea, can cause obstruction of the tracheal lumen of a left-sided DLT during ventilation of the dependent lung for a left thoracotomy.[81] Similarly, extrinsic compression or intraluminal obstruction of a mainstem bronchus that can interfere with endobronchial tube placement may only be evident on the CT scan. The major factors in successful lower airway management are anticipation and preparation based on the preoperative assessment. Management of lung isolation in patients with difficult upper and lower airways is discussed later in this chapter.

Prediction of Desaturation During One-Lung Ventilation

In the vast majority of cases, it is possible to determine those patients who are most at risk of desaturation during OLV for thoracic surgery. The factors that correlate with desaturation during OLV are listed in Box 53.7. In patients at high risk of desaturation, prophylactic measures can be used during OLV to decrease this risk. The most useful prophylactic measures are the use of CPAP (2–5 cm H_2O of oxygen) to the nonventilated lung and/or PEEP to the dependent lung (see "Treatment of Hypoxemia During One-Lung Ventilation").

BOX 53.7 Factors That Correlate With an Increased Risk of Desaturation During One-Lung Ventilation

1. High percentage of ventilation or perfusion to the operative lung on preoperative V/Q scan
2. Poor PaO_2 during two-lung ventilation, particularly in the lateral position intraoperatively
3. Right-sided thoracotomy
4. Normal preoperative spirometry (FEV_1 or FVC) or restrictive lung disease
5. Supine position during one-lung ventilation

FEV_1, forced expiratory volume in 1 second; *FVC*, forced vital capacity.

The most important predictor of PaO_2 during OLV is the PaO_2 during two-lung ventilation (TLV), specifically the intraoperative PaO_2 during TLV in the lateral position before OLV.[82] The proportion of perfusion or ventilation to the nonoperated lung on preoperative V/Q scans also correlates with the PaO_2 during OLV.[83] If the operative lung has little perfusion preoperatively because of unilateral disease, the patient is unlikely to desaturate during OLV. The side of the thoracotomy has an effect on PaO_2 during OLV. Because the left lung is 10% smaller than the right lung, there is less shunt when the left lung is collapsed. In a series of patients, the mean PaO_2 during left thoracotomy was approximately 70 mm Hg higher than during right thoracotomy.[84] Finally, the degree of obstructive lung disease correlates in an inverse fashion with PaO_2 during OLV. Other factors being equal, patients with more severe airflow limitation on preoperative spirometry tend to have a better PaO_2 during OLV than patients with normal spirometry (this is discussed later in "Anesthetic Management").[85]

Assessment for Repeat Thoracic Surgery

Patients who survive lung cancer surgery form a high-risk cohort who have a recurrence of the original tumor or develop a second primary tumor. The incidence of developing second primary lung tumors is estimated at 2% per year. The use of routine screening low-dose spiral CT scans probably increases the rate of early detection.[86] Patients who present for repeat thoracotomy should be assessed using the same framework as those who present for surgery the first time. Predicted values for postoperative respiratory function based on the preoperative lung mechanics, parenchymal function, exercise tolerance, and the amount of functioning lung tissue resected should be calculated and used to identify patients at increased risk.

Intraoperative Monitoring

A few points specific to intraoperative monitoring of the thoracic surgical patient need to be emphasized. The majority of these operations are major procedures of moderate duration (2–4 hours) and are performed with the patient in the lateral position and the hemithorax open. Thus consideration for monitoring and maintenance of body temperature

TABLE 53.4 Intraoperative Complications That Occur With Increased Frequency during Thoracotomy

Complication	Etiology
1. Hypoxemia	Intrapulmonary shunt during one-lung ventilation
2. Sudden severe hypotension	Surgical compression of the heart or great vessels
3. Sudden changes in ventilating pressure or volume	Movement of endobronchial tube/blocker, air leak
4. Arrhythmias	Direct mechanical irritation of the heart
5. Bronchospasm	Direct airway stimulation, increased frequency of reactive airway disease
6. Massive hemorrhage	Surgical blood loss from great vessels or inflamed pleura
7. Hypothermia	Heat loss from the open hemithorax

and fluid volume should be given to all of these cases. Because surgery is usually performed in the lateral position, monitors are initially placed with the patient in the supine position and have to be rechecked and repositioned after the patient is turned. It is difficult to add additional monitoring, particularly invasive vascular monitoring, after the case is started if complications arise. Thus the risk/benefit ratio often tends to favor being overly invasive at the outset. Choice of monitoring should be guided by a knowledge of which complications are likely to occur (Table 53.4).

OXYGENATION

Significant desaturation ($SpO_2 < 90\%$) during OLV occurs in 1% to 10% of the surgical population in spite of a high FiO_2 (1.0) (see "Management of One-Lung Ventilation" later). Pulse oximetry (SpO_2) has not negated the need for direct measurement of arterial P_aO_2 via intermittent blood gases in the majority of thoracotomy patients. The P_aO_2 value offers a more useful estimate of the margin of safety above desaturation than the S_pO_2. A patient with a TLV P_aO_2 greater than 400 mm Hg with an FiO_2 of 1.0 (or an equivalent P_aO_2/FiO_2 ratio) is unlikely to desaturate during OLV, whereas a patient with a P_aO_2 of 200 mm Hg is prone to desaturate during OLV, although both may have S_pO_2 values of 99% to 100%.

CAPNOMETRY

The end-tidal CO_2 ($P_{ET}CO_2$) is a less reliable indicator of the P_aCO_2 during OLV than during TLV, and the P_aCO_2-$P_{ET}CO_2$ gradient tends to increase during OLV. Although the $P_{ET}CO_2$ is less directly correlated with alveolar minute ventilation during OLV, because the $P_{ET}CO_2$ also reflects lung perfusion and cardiac output, it gives an indication of the relative changes in perfusion of the two lungs independently during position changes and during OLV.[87] As the patient is turned to the lateral position, the $P_{ET}CO_2$ of the nondependent lung will fall relative to the dependent lung, reflecting increased perfusion of the dependent lung and increased dead space of the nondependent lung. However, the fractional excretion of CO_2 will be higher from the nondependent lung in most patients because of the increased fractional ventilation of this lung. At the onset of OLV, the $P_{ET}CO_2$ of the dependent lung will usually fall transiently as all of the minute ventilation is transferred to this lung. The $P_{ET}CO_2$ will then rise as the fractional perfusion is increased to this dependent lung by collapse and pulmonary vasoconstriction of the nonventilated lung. If there is no correction of minute ventilation, the net result will be both an increased baseline P_aCO_2 and $P_{ET}CO_2$ with an increased gradient. Severe (>5 mm Hg) or prolonged decreases in $P_{ET}CO_2$ can indicate a maldistribution of perfusion between ventilated and nonventilated lungs and may be an early warning of a patient who will subsequently desaturate during OLV.

Invasive Hemodynamic Monitoring

ARTERIAL LINE

There is a significant incidence of transient severe hypotension from surgical compression of the heart or great vessels during intrathoracic procedures. For this reason, plus the utility of intermittent arterial blood gas sampling, it is useful have beat-to-beat assessment of systemic blood pressure during the majority of thoracic surgery cases. Naturally, exceptions occur during limited procedures, such as thoracoscopic resections in younger and healthier patients. For most thoracotomies, placement of a radial artery catheter can be in either the dependent or nondependent arm.

CENTRAL VENOUS PRESSURES

It is a common impression that CVP readings in the lateral position with the chest open are not reliable as a monitor of volume status. The CVP may be a useful monitor postoperatively, particularly for cases where fluid management is critical (e.g., pneumonectomies). A CVP may be required in some cases for vascular access or for vasopressor/inotrope infusions. It is our practice to routinely place CVP lines in pneumonectomy cases, complex procedures, or redo thoracotomies, but not for lesser resections unless there is significant other concurrent illness. Our choice is to use the right internal jugular vein to minimize the risk of pneumothorax for CVP access unless there is a contraindication. Internal jugular CVP data are not reliable in patients with superior vena cava obstruction.

PULMONARY ARTERY CATHETERS

Similar to CVP data, intraoperative pulmonary artery pressure may be a less accurate indicator of true left-heart preload in the lateral position with the chest open than in other clinical situations. This is partly because it is often initially not known if the catheter tip lies in the dependent or nondependent lung. In addition, it is possible that thermodilution cardiac output data may be unreliable if there are significant transient unilateral differences in perfusion between the lungs, as can occur during OLV. There is no consensus on the reliability of thermodilution cardiac output data during OLV.[88]

FIBEROPTIC BRONCHOSCOPY

Placement of DLTs and bronchial blockers is discussed later in the section on Lung Isolation. Significant malpositions of DLTs and blockers that can lead to desaturation during OLV are often not detected by auscultation or other traditional methods of confirming placement.[89] Placement of DLTs or blockers should be performed with fiberoptic bronchoscopic guidance and should be reconfirmed after placing the patient in the surgical position because a large number of these tubes/blockers migrate during repositioning of the patient.[90]

CONTINUOUS SPIROMETRY

The development of side-stream spirometry has made it possible to continuously monitor inspiratory and expiratory volumes, pressures, and flow interactions during one-lung anesthesia. This monitoring is particularly useful during pulmonary resection surgery. The breath-by-breath monitoring of inspired and expired tidal volumes gives early warning of accidental changes in the intraoperative position of a DLT, with loss of lung isolation if the expired volume suddenly decreases (there is normally a 20- to 30-mL/breath difference caused in part by the uptake of inspired oxygen). The development of a persistent end-expiratory flow during OLV, which correlates with the development of auto-PEEP, can be seen on the flow-volume loop.[91] Also, the ability to accurately measure differences in inspiratory and expiratory tidal volumes is extremely useful in assessing and managing air leaks during and after pulmonary resections.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

TEE allows the anesthesiologist to have a continuous real-time monitor of myocardial function and cardiac preload. This information is difficult to estimate intraoperatively in the lateral position from other hemodynamic monitors.[92] Potential indications for intraoperative TEE that apply to thoracic surgery include hemodynamic instability (Fig. 53.11), pericardial effusions, cardiac involvement by tumor, air emboli, pulmonary thromboendarterectomy, thoracic trauma, lung transplantation, and pleuropulmonary disease. A rare cause of hypoxemia associated with thoracic surgery is reversal of shunt flow through an undiagnosed patent foramen ovale. When PEEP (to 15 cm H_2O) was applied during controlled ventilation for nonthoracic surgery, 9% of the patients developed a right-to-left intracardiac shunt.[93] TEE should be capable of detecting situations in patients who might intraoperatively develop a right-to-left interatrial shunt during or after thoracic surgery.

Other Monitoring Technology

Cerebral oximetry ($SctO_2$) has been reported for intraoperative monitoring during OLV.[94] Elderly, debilitated patients are more likely to experience decreases in $SctO_2$ during OLV, and these are associated with decreases in SpO_2 and postoperative cognitive dysfunction. However, it has not been shown if any treatment for decreases in $SctO_2$ affects outcomes.

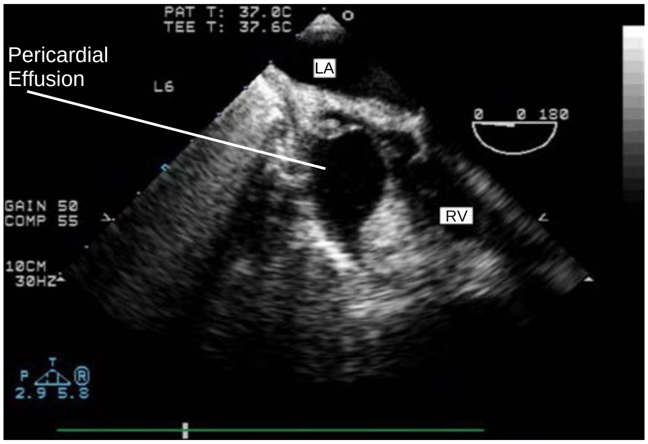

Fig. 53.11 Midesophageal transesophageal echocardiography (TEE) view of a patient with metastatic breast cancer who had a hemodynamic collapse after induction of general anesthesia for video-assisted thoracoscopic drainage of a left pleural effusion. *TEE* was performed for diagnosis of hemodynamic instability and revealed a previously undiagnosed large pericardial effusion. The "Pericardial Effusion" label shows complete collapse of the right atrium during systole as a result of the effusion, consistent with tamponade. The procedure was modified to include creation of a pericardial window. *LA*, Left atrium; *RV*, right ventricle.

Indirect Cardiac Output

It is not certain that goal-directed fluid therapy using indirect monitors of cardiac output or venous oxygen saturation improves outcomes in abdominal surgery.[95] At present, the validity of this technology as a valid guide for fluid management when the chest is open remains unclear.

Lung Isolation

Lung-isolation techniques are primarily designed to facilitate OLV in patients undergoing cardiac, thoracic, mediastinal, vascular, esophageal, or orthopedic procedures involving the chest cavity.[96] Lung isolation is also used to protect the lung from soiling by the contralateral lung in such cases as bronchopleural fistula, pulmonary hemorrhage, and whole-lung lavage. In addition, lung isolation can be used to provide differential patterns of ventilation in cases of unilateral reperfusion injury (after lung transplantation or pulmonary thromboendarterectomy) or in unilateral lung trauma.

Lung isolation can be achieved by three different methods: DLTs, bronchial blockers, or single-lumen endobronchial tubes (SLTs) (Table 53.5). The most common technique is with a DLT. The DLT is a bifurcated tube with both an endotracheal and an endobronchial lumen and can be used to achieve isolation of either the right or the left lung. The second method involves blockade of a mainstem bronchus to allow lung collapse distal to the occlusion. These bronchial blockers can be used with a standard endotracheal tube (ETT) or contained within a separate channel inside a modified SLT such as the Univent tube (LMA North America, San Diego, CA). The final option for lung isolation is to use either an SLT or endobronchial tube that is advanced into the contralateral mainstem bronchus, protecting this lung while allowing collapse of the lung on the

TABLE 53.5 Options for Lung Isolation

Options	Advantages	Disadvantages
Double-lumen tube 1. Direct laryngoscopy 2. Via tube exchanger 3. Fiberoptically	Easy to place successfully Repositioning rarely required Bronchoscopy to isolated lung Suction to isolated lung CPAP easily added Can alternate OLV to either lung easily Placement still possible if bronchoscopy not available Best device for absolute lung isolation	Size selection more difficult Difficult to place in patients with difficult airways or abnormal tracheas Not optimal for postoperative ventilation Potential laryngeal trauma Potential bronchial trauma
Bronchial blockers (BBs) Arndt Cohen Fuji EZ-Blocker	Size selection rarely an issue Easily added to regular ETT Allows ventilation during placement Easier placement in patients with difficult airways and in children Postoperative two-lung ventilation by withdrawing blocker Selective lobar lung isolation possible CPAP to isolated lung possible	More time needed for positioning Repositioning needed more often Bronchoscope essential for positioning Limited right lung isolation due to RUL anatomy Bronchoscopy to isolated lung impossible Minimal suction to isolated lung Difficult to alternate OLV to either lung
Univent tube	Same as BBs Less repositioning compared with BBs Rarely used	Same as for BBs ETT portion has higher air flow resistance than regular ETT ETT portion has larger diameter than regular ETT
Endobronchial tube	Like regular ETTs, easier placement in patients with difficult airways Longer than regular ETT Short cuff designed for lung isolation	Bronchoscopy necessary for placement Does not allow for bronchoscopy, suctioning, or CPAP to isolated lung Difficult right lung OLV
Endotracheal tube advanced into bronchus	Easier placement in patients with difficult airways	Does not allow for bronchoscopy, suctioning, or CPAP to isolated lung Cuff not designed for lung isolation Extremely difficult right OLV

CPAP, Continuous positive airway pressure; *ETT*, endotracheal tube; *OLV*, one-lung ventilation; *RUL*, right upper lobe.

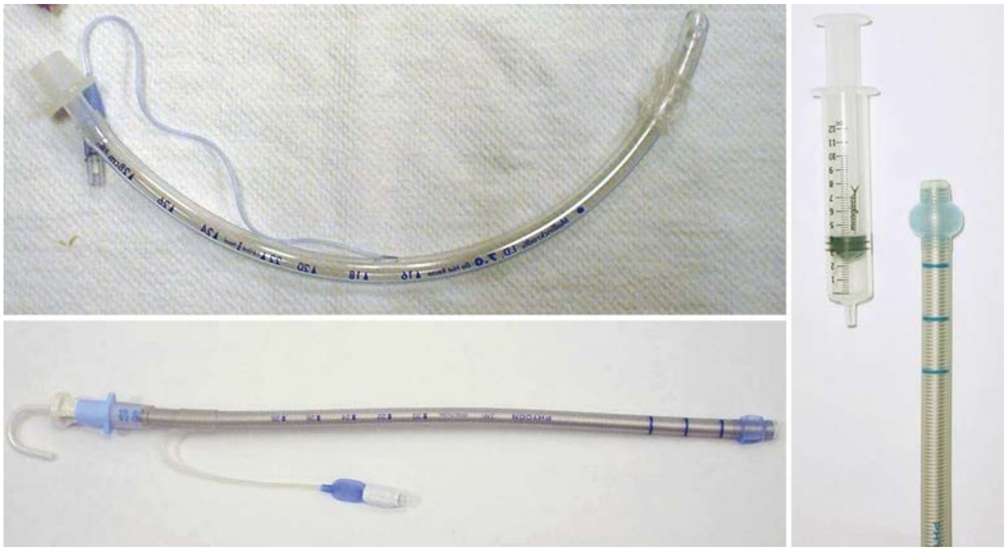

Fig. 53.12 Photographs of a standard single-lumen endotracheal tube (SLT) *(upper left)* and a specifically designed SLT (*lower left* and *right*). side of surgery (Fig. 53.12). This technique is rarely used today in adult practice (except in some cases of difficult airways, carinal resection, or after a pneumonectomy), owing to the limited access to the nonventilated lung and the difficulty in positioning a standard SLT in the bronchus. This technique is still used when needed in infants and small children: an uncuffed uncut pediatric-size ETT is advanced into the mainstem bronchus under direct guidance with an infant bronchoscope.

DOUBLE-LUMEN ENDOTRACHEAL TUBES

The design of the Carlens DLT for lung surgery in 1950 was a landmark in the development of thoracic anesthesia

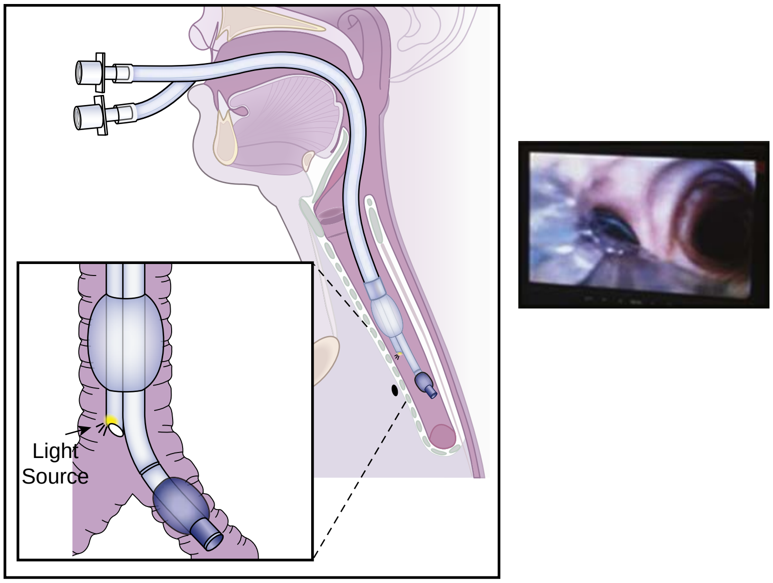

Fig. 53.13 The diagram on the left shows the placement of the VivaSight DLT in the tracheal and left main bronchus. The photograph on the right shows the view of the carina from the camera located beside the light source at the tracheal lumen orifice. *DLT*, Double-lumen tube. (Courtesy ETView Medical.)

because it allowed anesthesiologists to obtain reliable lung isolation in a majority of patients using only laryngoscopy and auscultation. However, the Carlens tube had a high flow resistance owing to the narrow lumina and the carinal hook was difficult to pass through the glottis in some patients. In the 1960s, Robertshaw introduced design modifications for separate left- and right-sided DLTs, removing the carinal hook and using larger lumina. In the 1980s, manufacturers introduced disposable DLTs made of polyvinyl chloride based on the design of the Robertshaw DLT. Among other subsequent improvements is the inclusion of radiographic markers near the endotracheal and endobronchial cuffs and a radiographic marker surrounding the ventilation slot for the right upper lobe bronchus for the right-sided DLT version. Bright blue, low-volume, low-pressure endobronchial cuffs are incorporated for easier visualization during fiberoptic bronchoscopy.

The VivaSight DLT (ETView Medical, Misgav, Israel) has an integrated camera, allowing continuous visualization of its position within the trachea.[97] This camera is embedded at the end of the endotracheal lumen, so that when connected to a screen monitor via a cable it allows a continuous view of the tracheal carina. In addition, this DLT device has an integrated flushing system that allows for in situ camera lens cleaning.[98] One of the advantages of the VivaSight DLT is that it allows continuous airway monitoring and its view facilitates immediate correction of DLT malpositions at the level of the tracheal carina. In order to maintain a good visualization with the VivaSight camera, it is recommended that a defogging solution be used prior to insertion. Fig. 53.13 shows the VivaSight DLT and monitor. Some centers have reported that the VivaSight DLT enables more rapid placement when compared to the conventional DLT and may eliminate the need for flexible fiberoptic bronchoscopy in some patients.[99] However, connecting the camera for prolonged periods of time in vitro may lead to melting the portion of the tube near the light source.

The ECOM-DLT (ECOM Medical, Inc., San Juan Capistrano, CA) contains multiple electrodes on the cuff and the tube that continuously measure the bioimpedance signal from the ascending aorta, in close proximity to the trachea. This device when connected to the ECOM monitor, in conjunction with an arterial catheter, provides cardiac output measurements (Fig. 53.14). This new ECOM-DLT has not been compared to other technology; however based on the original ECOM ETT,[100] it appears to be promising to derive hemodynamic parameters while in thoracic surgical patients.

Fuji Systems (Tokyo, Japan) has introduced the Silbroncho DLT, which is made of silicone. The unique characteristic of this device relies on the flexible wire-reinforced endobronchial tip. In addition, there is a beveled bronchial orifice and reduced bronchial cuff length that should increase the margin of safety when compared with other designs of DLTs. The Silbroncho DLT is particularly useful for performing a tube exchange from a single- to a double-lumen tube in combination with a video-laryngoscope and a tube exchange catheter (see “Difficult Airways and One-Lung Ventilation” later).[101]

Size Selection

Table 53.6 lists the different sizes of DLT, the appropriate fiberoptic bronchoscope sizes to be used, and the comparable diameters of SLTs. A properly sized, left-sided DLT should have a bronchial tip 1 to 2 mm smaller than the patient’s left bronchus diameter to allow for the space occupied by the deflated bronchial cuff. A study by Eberle and associates[102] used a three-dimensional image reconstruction of tracheobronchial anatomy from the spiral CT scans combined with superimposed transparencies of DLTs to predict proper size for a right- or left-sided DLT. Chest radiographs and CT scans are valuable tools for selection of proper DLT size in addition to their proven value in assessment of abnormal tracheobronchial anatomy and should be reviewed before the placement of the DLT (Fig. 53.15). A multidetector CT

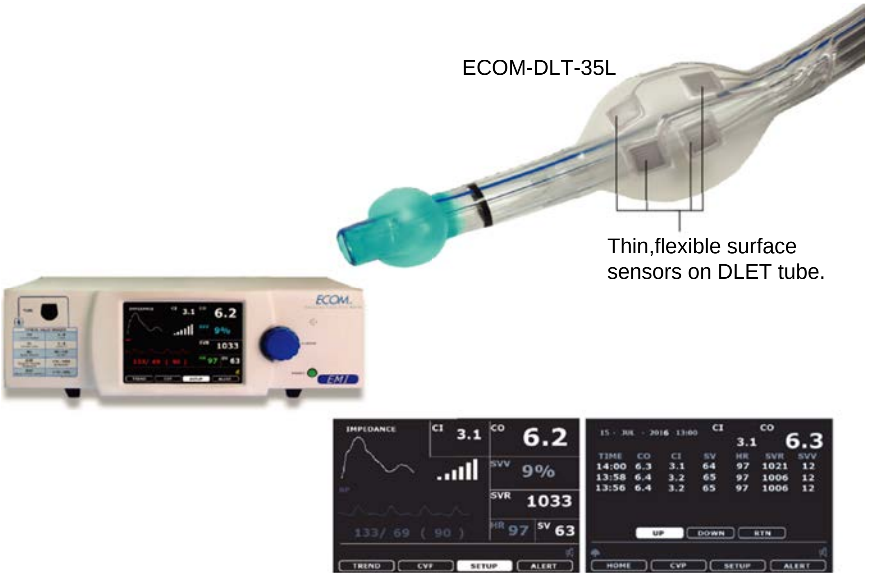

Fig. 53.14 The ECOM DLT has multiple electrodes on the cuff and the tube that continuously measure the bioimpedance signal from the ascending aorta with measurements of cardiac output. *DLT*, Double-lumen tube. (Courtesy ECOM Medical, Inc., San Juan Capistrano, CA.)

TABLE 53.6 Comparative Diameters of Single- and Double-Lumen Tubes

SINGLE-LUMEN TUBES		DOUBLE-LUMEN TUBES			
Internal Diameter (ID) (mm)	**External Diameter (ED) (mm)**	**French Size (Fr)**	**Double-lumen ED (mm)**	**Bronchial Lumen ID (mm)**	**FOB size (mm)**
6.5	8.9	26	8.7	3.2	2.4
7.0	9.5	28	9.3	3.4	2.4
8.0	10.8	32	10.7	3.5	2.4
8.5	11.4	35	11.7	4.3	≥3.5
9.0	12.1	37	12.3	4.5	≥3.5
9.5	12.8	39	13.0	4.9	≥3.5
10.0	13.5	41	13.7	5.4	≥3.5

ED, External diameter; *FOB*, fiberoptic bronchoscope; *ID*, internal diameter. Double-lumen ED = the approximate external diameter of the double-lumen portion of the tube. FOB size = the maximal diameter of fiberoptic bronchoscope that will pass through both lumens of a given size of double-lumen tube.

scan (MDCT) of the chest allows appreciation of any abnormal tracheobronchial anatomy before placement of a DLT. A simplified method of selection of DLT size is given in Table 53.7. It is important to appreciate that compared with SLTs, DLTs have a large external diameter (Fig. 53.16) and they should not be advanced against significant resistance.

Methods of Insertion

Two techniques are commonly used when inserting and placing a DLT. One is the blind technique: the DLT is passed with direct laryngoscopy and then turned 90 degrees counterclockwise (for a left-sided DLT placement) after the endobronchial cuff has passed beyond the vocal cords. The DLT should pass the glottis without any resistance. Seymour[103] showed that the mean diameter of the cricoid ring is approximately the same as that of the left mainstem bronchus. The optimal depth of insertion for a left-sided DLT is correlated with the patient's height in average-sized adults. In adults, depth, measured at the teeth, for a properly positioned DLT, will be approximately 12 + (patient height/10) cm.[104] In patients of Asian descent, many of whom are of shorter stature (<155 cm), patient height is not a good predictor of depth of insertion of a DLT[105] An inadvertently deep insertion of a DLT can lead to serious complications, including rupture of the left mainstem bronchus. Fig. 53.17 depicts the blind method technique for insertion of a left-sided DLT.

The direct vision technique uses bronchoscopic guidance, in which the tip of the endobronchial lumen is guided into the correct bronchus after the DLT passes the vocal cords using direct vision with a flexible fiberoptic bronchoscope. A study by Boucek and associates[106] comparing the blind technique versus fiberoptic bronchoscopy-guided technique showed that of the 32 patients who underwent the blind technique approach, primary success occurred in 27 patients and eventual success occurred in 30 patients. In contrast, in the 27 patients using the bronchoscopy-guided technique, primary success was achieved only in 21 patients and eventual success in 25 patients. Although both methods resulted in successful left mainstem bronchus placement in all patients, more time was required when fiberoptic bronchoscopy guidance technique was used (181 vs. 88 seconds).

Videolaryngoscopy is an important technique in the management of patients with expected or unexpected difficult airways. Clinical studies have shown that videolaryngoscopes improve visualization of laryngeal structures and facilitate insertion of a single-lumen ETT.[107] The use of the C-MAC videolaryngoscope has been compared with the Macintosh blade (the most common device used during laryngoscopy with a DLT) and the Miller blade during DLT intubation in patients with normal airways. The authors of this retrospective study showed that videolaryngoscopy views were similar to the views obtained with a Miller blade while passing a DLT.[108] In contrast the group that used a Macintosh blade had reported higher difficult intubations with the DLTs. TABLE 53.7 Selection of Double-Lumen Tube Size Based on Adult Patient's Sex and Height

Sex	Height (cm)	Size of Double-Lumen Tube (Fr)
Female	<160 (63 in)*	35
Female	>160	37
Male	<170 (67 in)**	39
Male	>170	41

*For females of short stature (<152 cm or 60 in), examine bronchial diameter on computed tomographic, scan, consider 32-Fr double-lumen tube.
**For males of short stature (<160 cm), consider 37-Fr double-lumen tube.

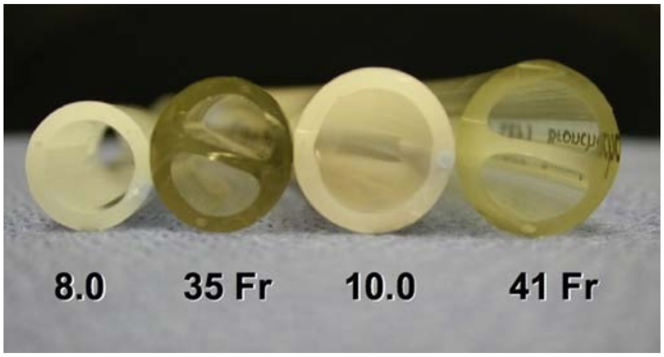

Fig. 53.16 Photograph of the cut cross sections of several SLTs and DLTs. The external diameter of a 35-Fr DLT is larger than that of an 8.0-mm (internal diameter) SLT, and a 41-Fr DLT is larger than a 10-mm SLT. *DLT*, Double-lumen tube; *SLT*, single-lumen tube. (Photo courtesy Dr. J Klafta.)

videolaryngoscope and the Macintosh direct laryngoscope for DLT intubation in patients with normal airways showed that the overall ease of successful intubation was higher with the Macintosh blade compared with the GlideScope[109]; also voice changes were less common in the Macintosh group. Therefore the authors do not recommend the routine use of the GlideScope in patients who have normal airways while using a DLT. In contrast, a study using the Airtraq DL videolaryngoscope during placement of DLT showed an improvement in exposure of the supraglottis during insertion of the DLT in patients with normal airways.[110] The usefulness of a videolaryngoscope while inserting a DLT will depend on the experience of the operator and the individual anatomy of the patient's airway.

RIGHT-SIDED DOUBLE-LUMEN ENDOBRONCHIAL TUBES

Although a left-sided DLT is used more commonly for most elective thoracic procedures,[111] there are specific clinical situations in which the use of a right-sided DLT is indicated (Box 53.8). The anatomic differences between the right and the left mainstem bronchus are reflected in the fundamentally different designs of the right-sided and left-sided DLTs. Because the right mainstem bronchus is shorter than the left bronchus, and because the right upper lobe bronchus originates at a distance of 1.5 to 2 cm from the carina, techniques using right endobronchial intubation must take into account the location and potential for obstruction of the orifice of the right upper lobe bronchus. The right-sided DLT incorporates a modified cuff and slot on the endobronchial lumen that allows ventilation for the right upper lobe (Fig. 53.18).[112]

Positioning of Double-Lumen Tubes

Auscultation alone is unreliable for confirmation of proper DLT placement. Auscultation (Fig. 53.19) and bronchoscopy should both be used each time a DLT is placed and again when the patient is repositioned. Fiberoptic bronchoscopy is performed first through the tracheal lumen to ensure that the endobronchial portion of the DLT is in the left bronchus and that there is no bronchial cuff herniation over the carina after inflation. Through the tracheal view, the blue endobronchial cuff ideally should be seen approximately 5 to 10 mm below the tracheal carina in the left bronchus. It is crucial to identify the take-off of the right upper lobe bronchus through the tracheal view. Going inside this right upper lobe with the bronchoscope should reveal three orifices (apical, anterior, and posterior). This is the only structure in the tracheobronchial tree that has three orifices. In the supine patient, the take-off of the right upper lobe is normally on the lateral wall of the right mainstem bronchus at the 3- to 4-o'clock position in relation to the main carina. Broncho-Cath tubes from Mallinckrodt have a radiopaque line encircling the tube. This line is proximal to the bronchial cuff and can be useful

BOX 53.8 **Indications for a Right-Sided Double-Lumen Tube**

- Distorted anatomy of the entrance of left mainstem bronchus
    - External or intraluminal tumor compression
    - Descending thoracic aortic aneurysm
- Site of surgery involving the left mainstem bronchus
    - Left lung transplantation
    - Left-sided tracheobronchial disruption
    - Left-sided pneumonectomy*
    - Left-sided sleeve resection

*It is possible to manage a left pneumonectomy with a left-sided DLT or bronchial blocker; however, the DLT or blocker will have to be withdrawn before stapling the left mainstem bronchus.

This is a common clinical practice pattern for using right-sided double-lumen tubes (DLTs) and assumes normal tracheobronchial anatomy, specifically a normal position of the orifice of the right upper lobe; however, some clinicians prefer to use right DLTs for all left-sided surgeries.

while positioning a left-sided DLT. The radiopaque marker is 4 cm from the distal tip of the endobronchial lumen. This marker reflects white during fiberoptic visualization and, when positioned slightly above the tracheal carina, should provide the necessary margin of safety for positioning into the left mainstem bronchus.[113] The next observation with the fiberoptic bronchoscope is made through the endobronchial lumen to check for patency of the tube and determination of margin of safety. The orifices of both the left upper and lower lobes must be identified to avoid distal impaction in the left lower lobe and occlusion of the left upper lobe (Fig. 53.20). Fig. 53.21 displays the tracheobronchial anatomy along with fiberoptic bronchoscopy findings from the endotracheal or endobronchial lumen for a left-sided DLT.

Problems Related to Double-Lumen Tubes

The most common problems and complications associated with the use of a DLT are malposition and airway trauma. A malpositioned DLT will fail to allow collapse of the lung, causing gas trapping during positive-pressure ventilation, or it may partially collapse the ventilated or dependent lung, producing hypoxemia. A common cause of malposition is dislodgment of the endobronchial cuff because of overinflation, surgical manipulation of the bronchus, or extension of the head and neck during or after patient positioning. Fiberoptic bronchoscopy is the recommended method to diagnose and correct intraoperative malposition of DLTs along with proper recognition of tracheobronchial anatomy. If a DLT is malpositioned in the supine or lateral decubitus position, there is a greater likelihood of hypoxemia during OLV. If a DLT is in the optimal position, but lung deflation is not completely achieved, a suction catheter should be passed to the side where lung collapse is supposed to occur. This suction will expedite lung deflation. The suction catheter must then be removed to avoid including it in a suture line.

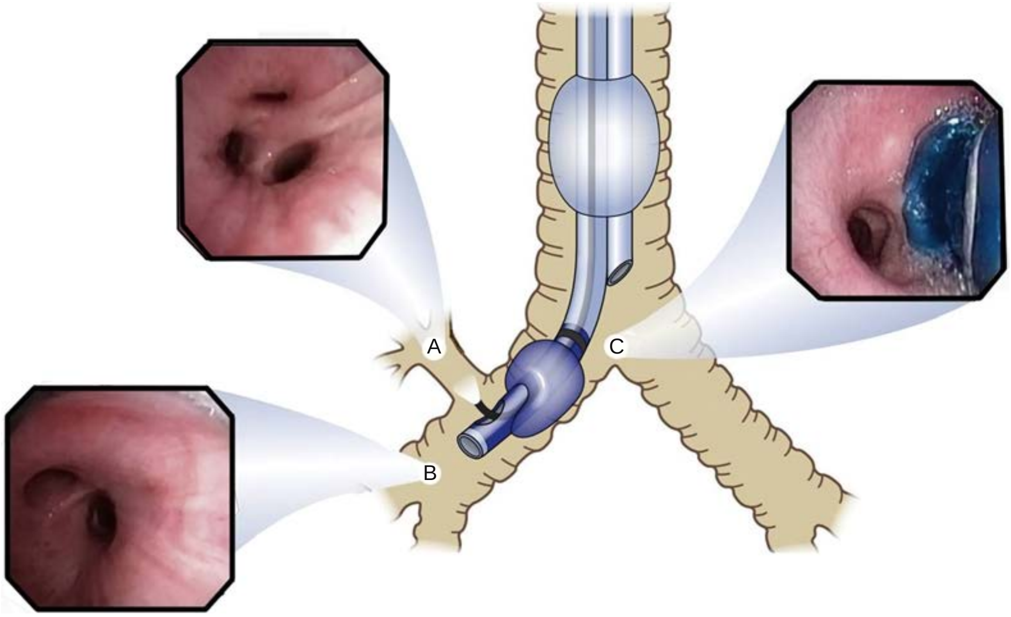

Fig. 53.18 Fiberoptic bronchoscopic examination of a Rusch right-sided DLT. (A) Slot of the bronchial lumen properly aligned within the entrance of the right upper lobe bronchus. (B) Part of the bronchus intermedius when the bronchoscope is advanced through the distal portion of the bronchial lumen. (C) Edge of the bronchial cuff at the entrance of the right mainstem bronchus when the bronchoscope is passed through the tracheal lumen. Fig. 53.19 A “3-step” method to confirm position of a left DLT by auscultation. Step 1, During bilateral ventilation, the tracheal cuff is inflated to the minimal volume that seals the air leak at the glottis. Auscultate to confirm bilateral ventilation. Step 2, The tracheal lumen of the DLT is clamped proximally (“clamp the short side short”) and the port distal to the clamp is opened. During ventilation via the bronchial lumen, the bronchial cuff is inflated to the minimal volume that seals the air leak from the open tracheal lumen port. Auscultate to confirm correct unilateral ventilation. Step 3, The tracheal lumen clamp is released and the port is closed. Auscultate to confirm resumption of bilateral breath sounds. *DLT*, Double-lumen tube. (Reproduced with permission from Slinger P. *Principles and Practice of Anesthesia for Thoracic Surgery*. New York: Springer; 2011.)

Airway trauma and rupture of the membranous part of the trachea or the bronchus is a potential complication with the use of DLTs.[114] Airway trauma can occur from an oversized DLT or when an undersized DLT migrates distally into the lobar bronchus and the main (i.e., tracheal) body of the DLT comes into the bronchus, producing lacerations or rupture of the airway. Airway damage during the use of DLTs can present as an unexpected air leak, subcutaneous emphysema, massive airway bleeding into the lumen of the DLT, or protrusion of the endotracheal or endobronchial cuffs into the surgical field, with visualization of this by the surgeon. If any of the aforementioned problems occur, a bronchoscopic examination and surgical repair should be performed. Another potential problem is the development of a tension pneumothorax in the dependent, ventilated lung during OLV.[115]

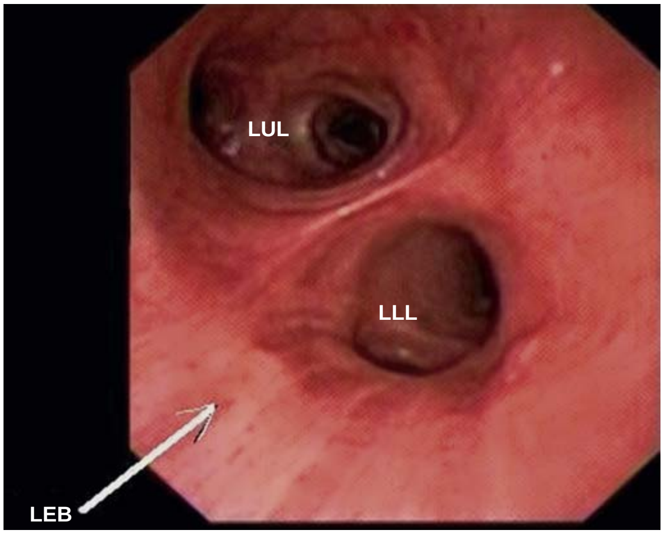

Fig. 53.20 The view from the distal bronchial lumen of a well-positioned left-sided DLT. Both the orifices of the left upper lobe *(LUL)* and left lower lobe *(LLL)* can be identified. Note the longitudinal elastic bundles (*LEB*, *arrow*). These extend down the posterior membranous walls of the trachea and mainstem bronchi. They are useful landmarks to orient the bronchoscopist to anterior-posterior directions. In the left mainstem bronchus, they extend into the left lower lobe and are a useful landmark to distinguish the lower from the upper lobe. *DLT*, Double-lumen tube.

BRONCHIAL BLOCKERS

An alternative method to achieve lung separation involves blockade of a mainstem bronchus to allow lung collapse distal to the occlusion (Fig. 53.22). Bronchial blockers also can be used selectively to achieve lobar collapse if necessary. Currently, there are several different bronchial blockers available to facilitate lung separation. These devices are either within a modified SLT as an enclosed bronchial blocker (Torque Control Blocker Univent; Vitaid, Lewinston, NY) or are used independently with a conventional SLT, such as the Arndt wire-guided endobronchial blocker (Cook Critical Care, Bloomington, IN), the Cohen tip-deflecting endobronchial blocker (Cook Critical Care), the Fuji Uniblocker (Vitaid), and the EZ-Blocker (Teleflex, Dresden, Germany).

There are specific conditions in which a bronchial blocker may be preferred to a DLT, such as patients with previous oral or neck surgery who present with a challenging airway and require lung separation for intrathoracic surgery. In these cases, the use of an SLT during an awake nasotracheal or orotracheal intubation or via tracheostomy secures the

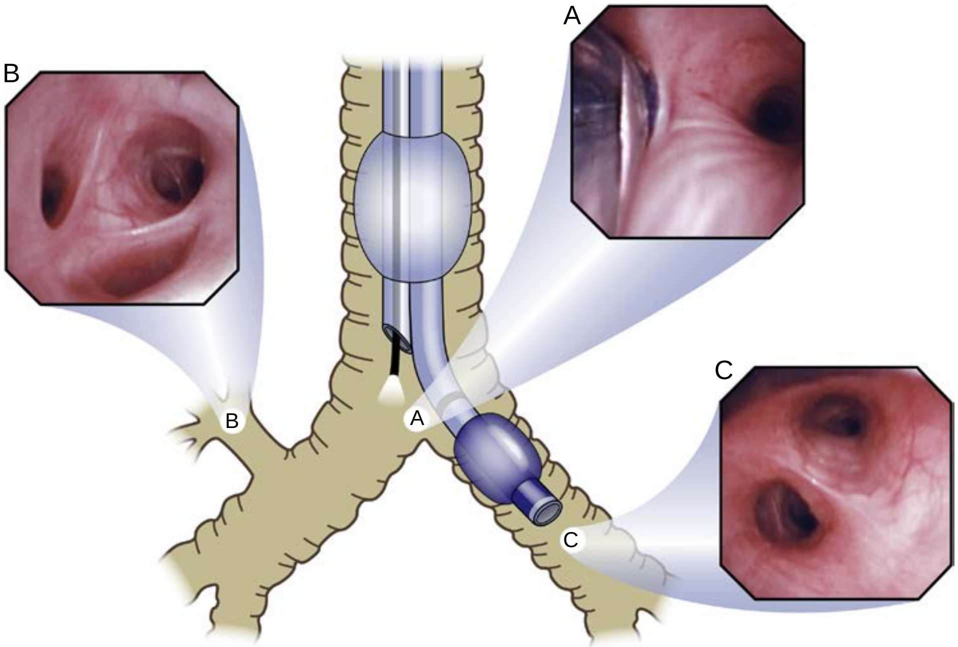

Fig. 53.21 Fiberoptic bronchoscopic examination of a Mallinckrodt left-sided DLT. (A) The edge of the endobronchial cuff around the entrance of the left mainstem bronchus when the bronchoscope is passed through the tracheal lumen. A white line marker is seen above the tracheal carina. (B) Clear view of the right upper lobe bronchus and its three orifices: apical, anterior, and posterior segments. (C) A clear view of the bronchial bifurcation (*left upper* and *left lower* bronchi) when the left-sided DLT is in the optimal position and the fiberoptic bronchoscope is being advanced through the endobronchial lumen. *DLT*, double-lumen tube. (Reproduced with permission from Slinger P. *Principles and Practice of Anesthesia for Thoracic Surgery*. New York: Springer; 2011.)

airway, and thereafter an independent bronchial blocker can be placed to achieve lung separation. Another group of patients who may benefit from the use of bronchial blockers are those cancer patients who have undergone a previous contralateral pulmonary resection. In such cases, selective lobar blockade with a bronchial blocker in the ipsilateral side improves oxygenation and facilitates surgical exposure. Blockers can be advanced over a guidewire placed with a fiberoptic bronchoscope into the required lobar bronchus. Bronchial blockers are most commonly used intraluminally (coaxially) with the SLT. The Cohen and Fuji Uniblockers can also be placed separately through the glottis or tracheostomy exterior to the SLT. This allows the use of a smaller SLT and is often an option in pediatrics. Another advantage of the bronchial blockers is when postoperative mechanical ventilation is being considered after prolonged thoracic or esophageal surgery. In many instances, these patients have an edematous upper airway at the end of the procedure. If a bronchial blocker is used, there is no need to change the SLT and there is no compromise of the airway if mechanical ventilation is needed in the postoperative period. Table 53.8 describes the characteristics of current bronchial blockers. The smallest internal diameter (ID) of an ETT that will allow passage of both a bronchial blocker and a fiberoptic bronchoscope depends on the diameters of the bronchoscope and blocker. For standard adult 9-Fr blockers, an ETT greater than or equal to 7.0 mm ID can be used with a bronchoscope less than 4.0 mm in diameter. Larger bronchoscopes will require an ETT greater than 7.5 mm ID. All blockers need to be well lubricated before placement.

Wire-Guided Endobronchial Blocker (Arndt Blocker)

Fig. 53.23*A* displays the Arndt blockers. The Arndt blocker has a retractable loop that is placed over the fiberoptic bronchoscope, which is then used to guide the blocker into place. The Arndt blockers usually advance easily into the right mainstem bronchus without the loop.

Cohen Endobronchial Blocker

The Cohen blocker (see Fig. 53.23*B*, left blocker) uses a wheel located in the most proximal part of the unit that deflects the tip of the distal part of the blocker into the desired bronchus. This blocker has been preangled at the distal tip to facilitate insertion into a target bronchus. On the distal shaft above the balloon, there is an arrow that, when seen with the fiberoptic bronchoscope, indicates in which direction the tip deflects. To position the Cohen blocker, the arrow is aligned with the

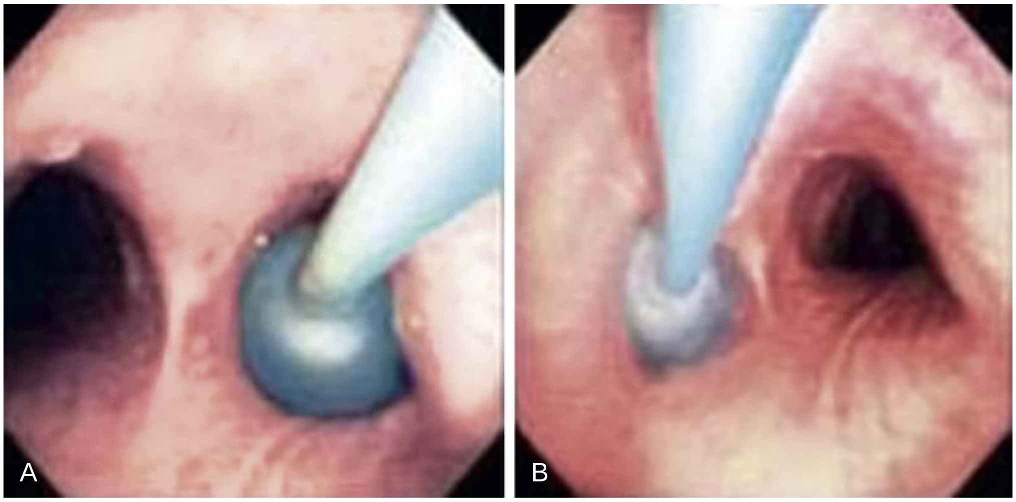

Fig. 53.22 Placement of a bronchial blocker. In the photos, correct positioning of a blocker in the right (A) and left (B) mainstem bronchi as seen through a fiberoptic bronchoscope just above the carina in the trachea. Fig. 53.23 (A) The original elliptical *(left)* and the newer spherical Arndt designs of bronchial blocker (Cook Critical Care, Bloomington, IN). (B) The Cohen *(left)* (Cook Critical Care, Bloomington, IN) and Fuji Uniblocker *(right)* (Vitaid, Lewinston, NY) bronchial blockers.

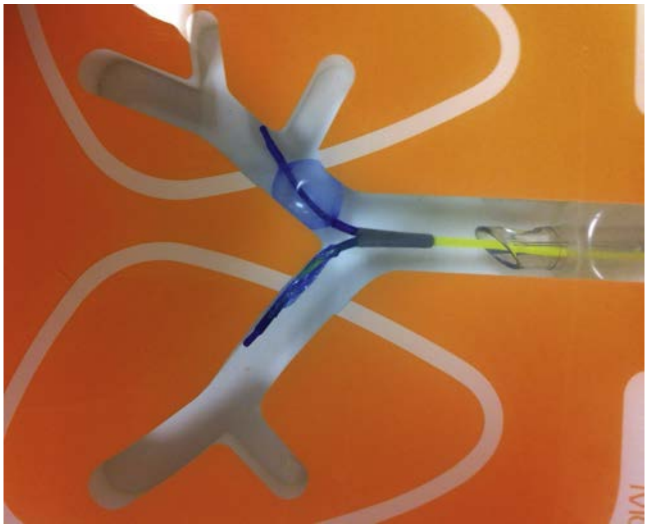

Fig. 53.24 The EZ-Blocker (Rusch, Teleflex) has two distal limbs each with a blocker-balloon that are positioned in each mainstem bronchus and is fixed at the carina. The two limbs are color-coded (*blue* and *yellow*) and the appropriate blocker is inflated via a matching colored pilot balloon.

bronchus to be intubated, the proximal wheel is turned to deflect the tip toward the desired side, and then the blocker is advanced with fiberoptic guidance.

Fuji Uniblocker

The Fuji Uniblocker (see Fig. 53.22*B*, right blocker) is an independent blocker that is made of silicone material and has a simple, fixed distal hockey-stick angulation to facilitate insertion. The blocker is simply rotated to the left or right as needed under fiberoptic bronchoscope guidance for placement in the required bronchus.

EZ-Blocker

The EZ-blocker (Fig. 53.24) is a recently introduced 7-Fr, 4-lumen catheter with a Y-shaped bifurcation. Each distal end has a balloon that can be guided into the right and left main bronchus. This device comes with its own multiport adaptor and is used through a 7.5 SLT. The end of the Y sits on the tracheal carina. Each distal end is positioned into the right and left bronchus, and the bronchial balloon is inflated in the operative side for lung isolation.

Complications Related to the Bronchial Blockers

Failure to achieve lung separation because of abnormal anatomy or lack of a seal within the bronchus has been reported.[116] Inclusion of the bronchial blocker or the distal wire loop of an Arndt blocker into the stapling line has been reported during a lobectomy[117] and required surgical reexploration after unsuccessful removal of the bronchial blocker after extubation. To avoid these mishaps, communication with the surgical team regarding the presence of a bronchial blocker in the surgical side is crucial. Clearly, the bronchial blocker needs to be withdrawn a few centimeters before stapling.

Another potentially dangerous complication with all bronchial blockers is that the inflated balloon may move and lodge above the carina or be accidentally inflated in the trachea. This leads to an inability to ventilate, hypoxia, and potentially cardiorespiratory arrest unless quickly recognized and the blocker deflated.[118] There is a report of more malpositions with the use of bronchial blockers when compared to DLTs.[119]

In a retrospective review of 302 consecutive cases from a single institution, no major complications were found with the use of different bronchial blockers during lung isolation.[120] A recent report described three cases where the balloon of the Fuji blocker failed to deflate at the conclusion of the surgery. In two of the cases, the already inflated bronchial blocker had to be removed along with the single-lumen ETT during extubation.[121] It is our recommendation to test the pilot and the balloon prior to use to ensure that the air that is injected is aspirated and the balloon completely deflates.

Difficult Airways and One-Lung Ventilation

A number of patients requiring OLV are identified during preoperative evaluation to have a potentially difficult airway.[122] Others present with unexpected difficulty to intubate after induction of anesthesia. Between 5% and 8% of patients with primary lung carcinoma also have a carcinoma of the pharynx, usually in the epiglottic area.[123] Many of these patients have had previous radiation therapy on the neck or previous airway surgery, such as hemimandibulectomy or hemiglossectomy, making intubation and achievement of OLV difficult due to distorted upper airway anatomy. Also, a patient who requires OLV might have distorted anatomy at or beyond the tracheal carina, such as descending thoracic aortic aneurysm compressing the entrance of the left mainstem bronchus or an intraluminal or extraluminal tumor near the tracheobronchial bifurcation that makes the insertion of a left-sided DLT relatively difficult or impossible. Such anomalies can be detected by reviewing the chest radiographs and CT scans of the chest. A flexible fiberoptic bronchoscopic examination is necessary to assess a distorted area of the airway before selection of a specific tube or blocker to achieve OLV.

In patients who require OLV and present with a difficult airway, the primary goal is to establish an airway with an SLT placed orally with the aid of a flexible fiberoptic bronchoscope, after appropriate airway anesthesia is achieved. In selected patients who seem easy to ventilate, this may be performed after induction of anesthesia with a bronchoscope or with a videolaryngoscope.[124] Once the SLT is in place, an independent bronchial blocker can be passed. If the patient requires OLV and cannot be intubated orally, an awake nasotracheal intubation can be performed with an SLT and, once the airway is established, then a bronchial blocker can be used.

An alternative to achieve OLV in a patient with a difficult airway is to intubate the patient's trachea with an SLT; then a DLT-SLT tube-exchange catheter can be used to replace the existing SLT with a DLT after general anesthesia is induced. For a DLT the exchange catheter should be at least 83 cm. A 14-Fr exchange catheter can be used for 41-Fr and 39-Fr DLTs; for 37-Fr or 35-Fr DLTs an 11-Fr exchange catheter is used. Specially designed exchange catheters for DLTs are available with a softer distal tip to try to decrease the risk of distal airway trauma (e.g., Cook Exchange Catheter, Cook Critical Care).

The exchange catheter, SLT, and the DLT combination should be tested in vitro before the exchange. A sniffing position facilitates tube exchange. After the exchange catheter is lubricated, it is advanced through an SLT. The catheter should not be inserted deeper than 24 cm at the lips to avoid accidental rupture or laceration of the trachea or bronchi. After cuff deflation, the SLT is withdrawn. Then the endobronchial lumen of the DLT is advanced over the exchange catheter. It is optimal to use a videolaryngoscope during the tube exchange to guide the DLT through the glottis under direct vision (Fig. 53.25). If a videolaryngoscope is not available, having an assistant perform standard laryngoscopy during tube exchange partially straightens out the alignment of the oropharynx and glottis and facilitates the exchange. Proper final position of the DLT is then achieved with auscultation and bronchoscopy.

Lung-Isolation Techniques in Patients With a Tracheostomy in Place

Placement of a DLT through a tracheostomy stoma may be prone to malposition because the upper airway has been shortened and the conventional DLT may be too long. Before placing any lung isolation devices through a tracheostomy stoma it is important to consider whether it is a fresh stoma (i.e., a few days old, when the airway can be lost immediately on decannulation) versus a chronic tracheostomy. The alternatives to achieve OLV in a tracheostomized patient include (1) insertion of an SLT followed by an independent bronchial blocker passed coaxially or externally to the SLT[125]; (2) the use of a disposable cuffed tracheostomy cannula with an independent bronchial blocker; (3) replacement of the tracheostomy cannula with a specially designed short DLT such as the Naruke DLT, which is made for use in tracheostomized patients[126]; (4) placement of a small DLT through the tracheostomy stoma; or (5) if possible, oral access to the airway for standard placement of a DLT or blocker (this is occasionally an option in patients on prolonged mechanical ventilation for respiratory failure or postoperative complications).

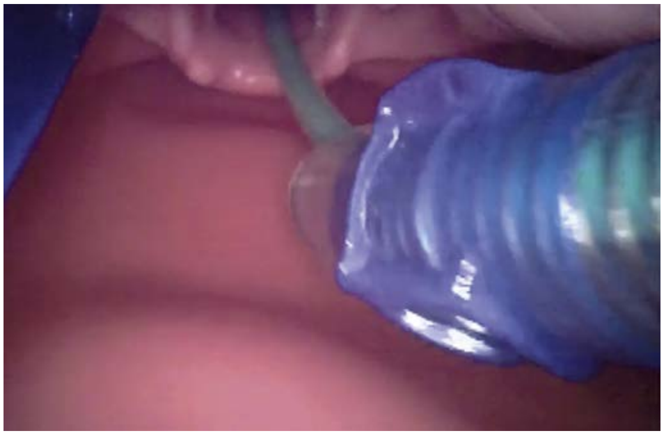

Fig. 53.25 A DLT is placed over a tube-exchange catheter using a video laryngoscope for guidance. The green SLT-DLT tube-exchange catheter (Cook Critical Care, Bloomington, IN) was passed initially through the SLT, which has been withdrawn (before the photo was taken) and the catheter then passed retrograde through the bronchial lumen of a DLT, which is advanced under direct vision through the glottis. The DLT in this picture (Fuji, Phycon, Vitaid, Lewinston, NY) has a bevel on the distal bronchial orifice and a flexible bronchial lumen that facilitates this procedure. *DLT*, Double-lumen tube; *SLT*, single-lumen tube.

In summary, the optimal method of lung isolation will depend on a number of factors, including the patient's airway anatomy, the indication for lung isolation, the available equipment, and the training of the anesthesiologist. Whatever method of lung isolation is used, the "ABCs" of lung isolation are:

Anatomy. Know the tracheobronchial anatomy. One of the major problems that many anesthesiologists have in achieving satisfactory lung isolation is due to lack of familiarity with distal airway anatomy (Fig. 53.26).

Bronchoscopy. Whenever possible use a fiberoptic bronchoscope to position endobronchial tubes and blockers. The ability to perform fiberoptic bronchoscopy is now a fundamental skill needed by all anesthesiologists providing anesthesia for thoracic surgery. An online bronchoscopy simulator has been developed to help train anesthesiologists in positioning DLTs and blockers. This simulator, which uses real-time video, is available without cost at www.thoracicanesthesia.com.

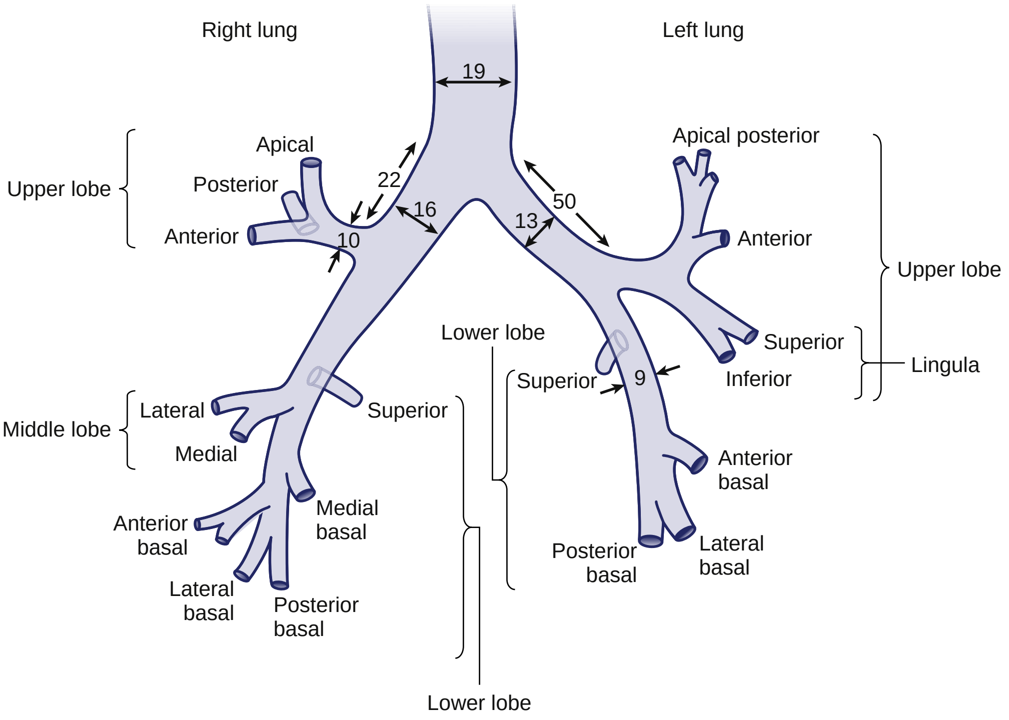

Fig. 53.26 Diagram of the tracheobronchial tree. Mean lengths and diameters are shown in millimeters. Note that the right middle lobe bronchus exits directly anteriorly and the superior segments (some authors refer to these as the "apical" segments) of the lower lobes exit directly posteriorly. Using the apical designation, on the right side the segmental bronchi in a rostral to caudal sequence give the mnemonic "A PALM A MAPL". (Reproduced with permission from Slinger P. *Principles and Practice of Anesthesia for Thoracic Surgery*. New York: Springer; 2011.)

Chest imaging. The anesthesiologist should always look at the chest imaging before placement of a DLT or blocker. Abnormalities of the lower airway can often be identified in advance, and this will have an impact on the selection of the optimal method of lung isolation for a specific case (see Figs. 53.10 and 53.15).

POSITIONING

The majority of thoracic procedures are performed in the lateral position, most often the lateral decubitus position, but depending on the surgical technique a supine, semisupine or semiprone lateral position may be used. These lateral positions have specific implications for the anesthesiologist.

Position Change

It is awkward to induce anesthesia in the lateral position. Thus monitors will be placed and anesthesia will usually be induced in the supine position and the anesthetized patient will then be repositioned for surgery. It is possible to induce anesthesia in the lateral position and this may rarely be indicated with unilateral lung diseases such as bronchiectasis or hemoptysis until lung isolation can be achieved. However, even these patients will then have to be repositioned and the diseased lung turned to the nondependent side.

Because of the loss of venous vascular tone in the anesthetized patient, it is not uncommon to see hypotension when turning the patient to or from the lateral position. All lines and monitors will have to be secured during position change and their function reassessed after repositioning. The anesthesiologist should take responsibility for the head, neck, and airway during position change and must be in charge of the operating team to direct repositioning. It is useful to make an initial "head-to-toe" survey of the patient after induction and intubation checking oxygenation, ventilation, hemodynamics, lines, monitors, and potential nerve injuries. This survey then must be repeated after repositioning. It is nearly impossible to avoid some movement of a DLT or bronchial blocker during repositioning. Certainly the patient's head, neck, and endobronchial tube should be turned "en-bloc" with the patient's thoracolumbar spine. However, the margin of error in positioning endobronchial tubes or blockers is often so narrow that even very small movements can have significant clinical implications. The carina and mediastinum may shift independently with repositioning and this can lead to proximal misplacement of a previously well-positioned tube. Endobronchial tube/blocker position and the adequacy of ventilation must be rechecked by auscultation and fiberoptic bronchoscopy after patient repositioning.

In addition, with the introduction of robotics for thoracic surgery careful attention must be given to airway devices because changes in patient position required for robotic surgery have the potential to cause malposition of airway devices. In robotic thoracic surgery access to the airway in midoperation can be very difficult.[127]

Neurovascular Complications

There is a specific set of nerve and vascular injuries related to the lateral position that must be appreciated. The brachial plexus is the site of the majority of intraoperative nerve injuries related to the lateral position.[128] These are basically of two varieties: the majority are compression injuries of the brachial plexus of the dependent arm but there is also significant risk of stretch injuries to the brachial plexus of the nondependent arm. The brachial plexus is fixed at two

BOX 53.9 Factors That Contribute to Brachial Plexus Injury in the Lateral Position

a. Dependent arm (compression injuries)
   1. Arm directly under thorax
   2. Pressure on clavicle into retroclavicular space
   3. Cervical rib
   4. Caudal migration of thorax padding into the axilla*

b. Nondependent arm (stretch injuries)
   1. Lateral flexion of cervical spine
   2. Excessive abduction of arm (>90 degrees)
   3. Semiprone or semisupine repositioning after arm fixed to a support

*Unfortunately, this padding under the thorax is misnamed an "axillary roll" in some institutions. This padding absolutely should NOT be placed in the axilla.

points: proximally by the transverse process of the cervical vertebrae and distally by the axillary fascia. This two-point fixation, plus the extreme mobility of neighboring skeletal and muscular structures, makes the brachial plexus extremely liable to injury (Box 53.9). The patient should be positioned with padding under the dependent thorax to keep the weight of the upper body off the dependent arm brachial plexus. However, this padding will exacerbate the pressure on the brachial plexus if it migrates superiorly into the axilla.

The arms should not be abducted beyond 90 degrees and should not be extended posteriorly beyond the neutral position nor flexed anteriorly greater than 90 degrees. Fortunately, the majority of these nerve injuries resolve spontaneously over a period of months. Anterior flexion of the arm at the shoulder (circumduction) across the chest or lateral flexion of the neck toward the opposite side can cause a traction injury of the suprascapular nerve.[129] This causes a deep, poorly circumscribed pain of posterior and lateral aspects of the shoulder and may be responsible for some cases of postthoracotomy shoulder pain.

It is very easy, after repositioning the patient in the lateral decubitus position, to cause excessive lateral flexion of the cervical spine because of improper positioning of the patient's head. This malpositioning, which exacerbates brachial plexus traction, can cause a "whiplash" syndrome and can be difficult to appreciate from the head of the operating table, particularly after the surgical drapes have been placed. It is useful for the anesthesiologist to survey the patient from the side of the table immediately after turning to ensure that the entire vertebral column is aligned properly.

The dependent leg should be slightly flexed with padding under the knee to protect the peroneal nerve lateral to the proximal head of the fibula. The nondependent leg is placed in a neutral extended position and padding placed between it and the dependent leg. The dependent leg must be observed for vascular compression. Excessively tight strapping at the hip level can compress the sciatic nerve of the nondependent leg. Other sites particularly liable for neurovascular injury in the lateral position are the dependent ear pinna and eye. A "head-to-toe" protocol to monitor for possible neurovascular injuries related to the lateral decubitus position is presented in Box 53.10.

BOX 53.10 Neurovascular Injuries Specific to the Lateral Position: Routine "Head-to-Toe" Survey

1. Dependent eye
2. Dependent ear pinna
3. Cervical spine in line with thoracic spine
4. Dependent arm: (i) brachial plexus, (ii) circulation
5. Nondependent arm*: (i) brachial plexus, (ii) circulation
6. Dependent and nondependent suprascapular nerves
7. Nondependent leg sciatic nerve
8. Dependent leg: (i) peroneal nerve, (ii) circulation

*Neurovascular injuries of the nondependent arm are more likely to occur if the arm is suspended or held in an independently positioned arm rest.

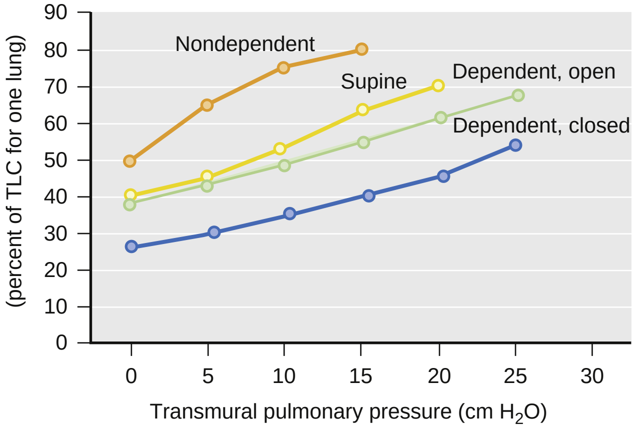

Fig. 53.27 Changes in the compliance of a single lung during position changes in an anesthetized, paralyzed patient during controlled mechanical ventilation. These compliance changes are responsible for the resulting differences in ventilation between the lungs that occur in the lateral position. Note: the compliance of the dependent lung is increased when the nondependent hemithorax is open versus closed. *TLC*, Total lung capacity.

Physiologic Changes in the Lateral Position

Ventilation. Significant changes in ventilation develop between the lungs when the patient is placed in the lateral position.[130] The compliance curves of the two lungs are different because of their difference in sizes. The lateral position, anesthesia, paralysis, and opening the thorax all combine to magnify these differences between the lungs (Fig. 53.27). The compliance curve (change in volume vs. change in pressure) of a lung depends on the balance of two "springs": the chest wall (normally distending the lung) and the elastic recoil of the lung itself. Any factor that changes the mechanics of either of these springs places the lung on a different compliance curve.[131]

In a healthy, conscious, spontaneously breathing patient, the ventilation of the dependent lung will increase approximately 10% when the patient is turned to the lateral position. Once the patient is anesthetized and paralyzed, the ventilation of the dependent lung will then decrease 15%. Although the ventilation will not change significantly once the nondependent hemithorax is open, the FRC of this nondependent lung will tend to increase approximately 10%. These changes depend on the method used for ventilation in the individual patient.

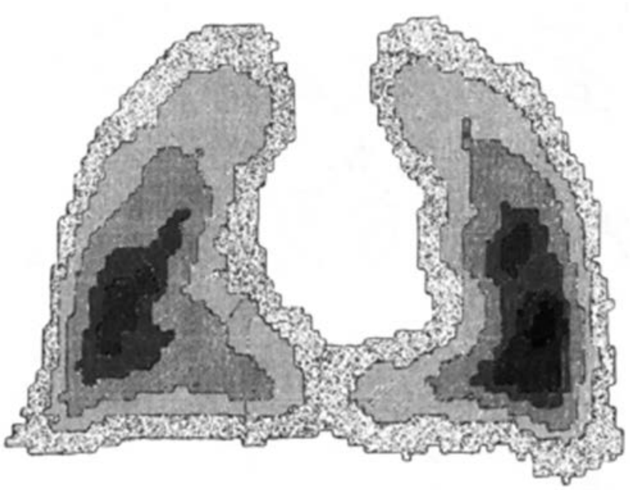

Fig. 53.28 In vivo perfusion lung scanning in the upright position demonstrates a predominant central to peripheral distribution of pulmonary blood flow in addition to a gravitational effect which also increases the blood flow in dependent lung regions. (Reproduced with permission from Slinger P. *Principles and Practice of Anesthesia for Thoracic Surgery*. New York: Springer; 2011.)

When the chest is open, due to disruption of the chest wall, both lungs tend to collapse to a minimal lung volume if expiration is prolonged. Thus the end-expiratory volume of each lung is directly a function of the time allowed for expiration. The compliance of the entire respiratory system increases significantly once the nondependent hemithorax is open.

Because of the fall in FRC and compliance of the dependent lung in the lateral position, application of PEEP selectively to this lung only (using a DLT and two anesthetic circuits), will improve gas exchange.[132] This is different than the effect of nonselectively applying PEEP to both lungs in the lateral position where PEEP tends to preferentially distribute to the most compliant lung regions and will tend to hyperinflate the nondependent lung without causing any improvement in gas exchange.[133]

Atelectasis will develop in an average of 6% of the lung parenchyma after induction of anesthesia in the supine position. This atelectasis will be evenly distributed in the dependent portions of both lungs.[134] Turning the patient to the lateral position, there will be a slight decrease of total atelectasis to 5% of lung volume but this will now be concentrated totally in the dependent lung.

Perfusion. Gravity has some effect on distribution of pulmonary blood flow. In the lateral position, the blood flow to the dependent lung is generally thought to be increased by 10% compared to the same lung in the supine position.[135] However, the distribution of pulmonary blood flow in various positions may be more related to inherent pulmonary vascular anatomy than to gravity (Fig. 53.28).[136] The matching of ventilation and perfusion will usually be decreased in the lateral position compared to the supine position during anesthesia. Pulmonary arteriovenous shunt during general anesthesia will usually increase from approximately 5% in the supine position to 10% to 15% in the lateral position.[137]

BOX 53.11 **Fluid Management for Pulmonary Resection Surgery**

- Total positive fluid balance in the first 24-h perioperative period should not exceed 20 mL/kg
- For an average adult patient, crystalloid administration should be limited to less than 3 L in the first 24 h
- No fluid administration for third-space fluid losses during pulmonary resection
- Urine output greater than 0.5 mL/kg/h is unnecessary
- If increased tissue perfusion is needed postoperatively, it is preferable to use invasive monitoring and inotropes rather than to cause fluid overload

Anesthetic Management

The development of thoracic anesthesia and thoracic surgery was delayed more than 50 years after the introduction of ether because anesthesiologists could not manage patients during mask anesthesia with spontaneous ventilation and an open chest. These patients developed what was originally called the “pneumothorax syndrome.”[138] The respiratory systems of mammals do not function adequately with an open hemithorax due to two physiologic problems. First, paradoxical ventilation (also called “pendelluft”) in which gas moves into the open-chest lung from the intact lung during expiration and then reverses flow during inspiration. This leads to hypercapnia and hypoxemia. And second, due to the swinging motion of the mediastinum between the hemithoraces during the respiratory cycle, which interferes with cardiac preload and causes hemodynamic instability. In the early 1900s, several pioneers such as the New Orleans surgeon Matas advocated positive-pressure ventilation and a primitive form of endotracheal ventilation, which had been demonstrated to be safe in animal experiments, for thoracic anesthesia. Modern methods, incorporating OLV, have evolved from this. Essentially any anesthetic technique that provides safe and stable general anesthesia for major surgery can and has been used for lung resection.

FLUID MANAGEMENT

Because of hydrostatic effects, excessive administration of intravenous fluids can cause increased shunting and subsequently lead to pulmonary edema of the dependent lung, particularly during prolonged surgery.[139] Because the dependent lung is the lung that must carry on gas exchange during OLV, it is best to be as judicious as possible with fluid administration. Intravenous fluids are administered to replace volume deficits and for maintenance only during lung resection anesthesia. No volume is given for theoretical “third space” losses (Box 53.11).[140]

TEMPERATURE

Maintenance of body temperature can be a problem during thoracic surgery because of heat loss from the open hemithorax. This is particularly a problem at the extremes of the age spectrum. Most of the body’s physiological functions, including HPV, are inhibited during hypothermia.

Increasing the ambient room temperature, fluid warmers, and the use of lower and/or upper-body forced-air patient warmers are the best methods to prevent inadvertent intraoperative hypothermia.

PREVENTION OF BRONCHOSPASM

Because of the high incidence of coexisting reactive airways' disease in the thoracic surgical population, it is advisable to use an anesthetic technique that decreases bronchial irritability. This is particularly important because the added airway manipulation caused by placement of a DLT or bronchial blocker is a potent trigger for bronchoconstriction. The principles of anesthetic management are the same as they are for any asthmatic patient: avoid manipulation of the airway in a lightly anesthetized patient, use bronchodilating anesthetics, and avoid drugs that release histamine. For intravenous induction of anesthesia, either propofol or ketamine can be expected to diminish bronchospasm. This benefit is not seen with barbiturate, opioid, benzodiazepine, or etomidate intravenous induction. For maintenance of anesthesia, propofol and/or any of the volatile anesthetics will diminish bronchial reactivity. Sevoflurane may be the most potent bronchodilator of the volatile anesthetics.[141]

CORONARY ARTERY DISEASE

Because the lung resection population is largely elderly and smokers, there is a high coincidence of coronary artery disease. This consideration will be a major factor in the choice of the anesthetic technique for most thoracic patients. The anesthetic technique should optimize the myocardial oxygen supply/demand ratio by maintaining arterial oxygenation and diastolic blood pressure while avoiding unnecessary increases in cardiac output and heart rate. Thoracic epidural anesthesia/analgesia may aid in this (see Postoperative Analgesia later).

Management of One-Lung Ventilation

During OLV, the anesthesiologist has the unique and often conflicting goals of trying to maximize atelectasis in the nonventilated lung to improve surgical access while trying to avoid atelectasis in the ventilated lung (usually the dependent lung) to optimize gas exchange. The gas mixture in the nonventilated lung immediately before OLV has a significant effect on the speed of collapse of this lung. Because of its low blood-gas solubility, nitrogen (or an air-oxygen mixture) will delay collapse of this lung (Fig. 53.29).[142] This is particularly a problem at the start of VATS surgery when surgical visualization in the operative hemithorax is limited and in patients with emphysema who have delayed collapse of the nonventilated lung because of decreased lung elastic recoil. It is important to thoroughly denitrogenate the operative lung, by ventilating with oxygen, immediately before it is allowed to collapse. Although nitrous oxide (N_2O) is even more effective than oxygen in speeding lung collapse, for the reasons just cited, it is not commonly used in thoracic anesthesia because many patients may have blebs or bullae.

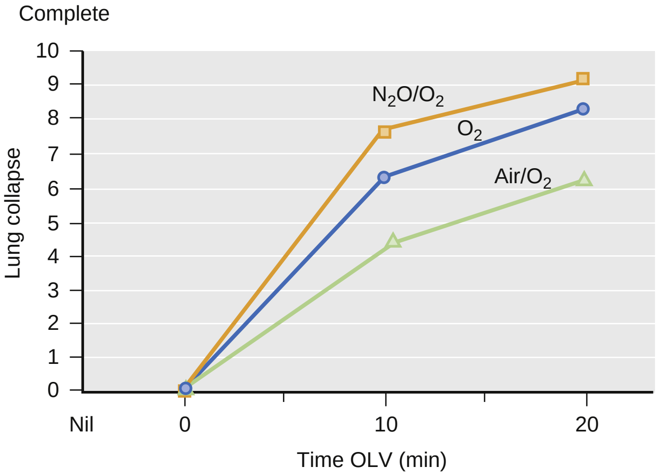

Fig. 53.29 The effects of the gas mixture used during two-lung ventilation *(TLV)*, immediately before one-lung venation *(OLV)*, on the speed of collapse of the nonventilated lung during OLV. $O_2 = FiO_2$ 1.0; N_2O/O_2 = nitrous oxide/oxygen 60/40; air/O_2 = air/oxygen FiO_2 0.4. All patients were ventilated with a FiO_2 of 1.0 during OLV. The poorly soluble nitrogen in the air/oxygen mixture delays collapse of the nonventilated lung. (Based on data from Ko R, et al. *Anesth Analg*. 2009;108:1029.)

Also, during the period of two-lung anesthesia before the start of OLV, atelectasis will develop in the dependent lung. It is useful to perform a recruitment maneuver to the dependent lung (similar to a Valsalva maneuver, holding the lung at an end-inspiratory pressure of 20 cm H_2O for 15–20 seconds) immediately after the start of OLV to decrease this atelectasis. Recruitment is important to maintain PaO_2 levels during subsequent OLV.[143]

HYPOXEMIA

A major concern that influences anesthetic management for thoracic surgery is the occurrence of hypoxemia during OLV. There is no universally acceptable figure for the safest lower limit of oxygen saturation during OLV. A saturation greater than or equal to 90% ($PaO_2 > 60$ mm Hg) is commonly accepted, and for brief periods a saturation in the high 80%s may be acceptable in patients without significant comorbidity. However, the lowest acceptable saturation will be higher in patients with organs at risk of hypoxia because of limited regional blood flow (e.g., coronary or cerebrovascular disease) and in patients with limited oxygen transport (e.g., anemia or decreased cardiopulmonary reserve). It has been shown that during OLV patients with COPD desaturate more quickly during isovolemic hemodilution than normal patients.[144]

Previously, hypoxemia occurred frequently during OLV. Reports for the period between 1950 and 1980 describe an incidence of hypoxemia (arterial saturation < 90%) of 20% to 25%.[145] More recent reports describe an incidence of less than 5%.[146] This improvement is most likely a result of several factors: improved lung isolation techniques such as routine fiberoscopy to prevent lobar obstruction from DLTs, improved anesthetic drugs that cause less inhibition of HPV, and better understanding of the pathophysiology of OLV. The pathophysiology of OLV involves the body's ability to redistribute pulmonary blood flow to the ventilated lung. Several factors aid and impede this redistribution

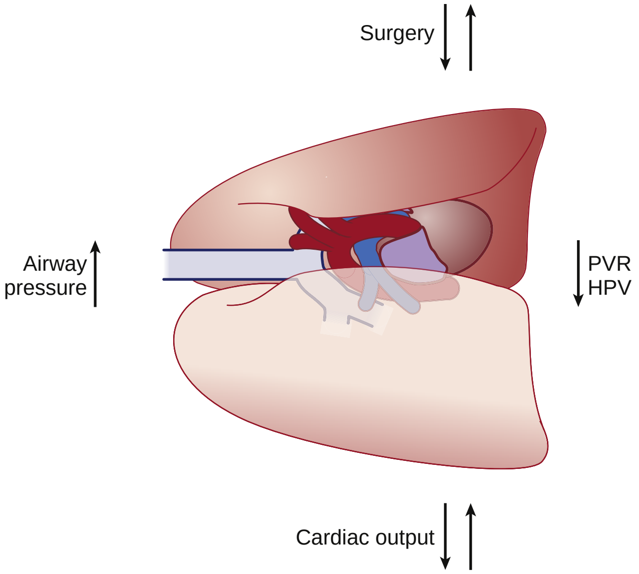

Fig. 53.30 Factors affecting the distribution of pulmonary blood flow during one-lung ventilation. Hypoxic pulmonary vasoconstriction *(HPV)*, and the collapse of the nonventilated lung, which increases pulmonary vascular resistance *(PVR)*, tend to distribute blood flow toward the ventilated lung. The airway pressure gradient between the ventilated and nonventilated thoraces tends to encourage blood flow to the nonventilated lung. Surgery and cardiac output can have variable effects, either increasing or decreasing the proportional flow to the ventilated lung.

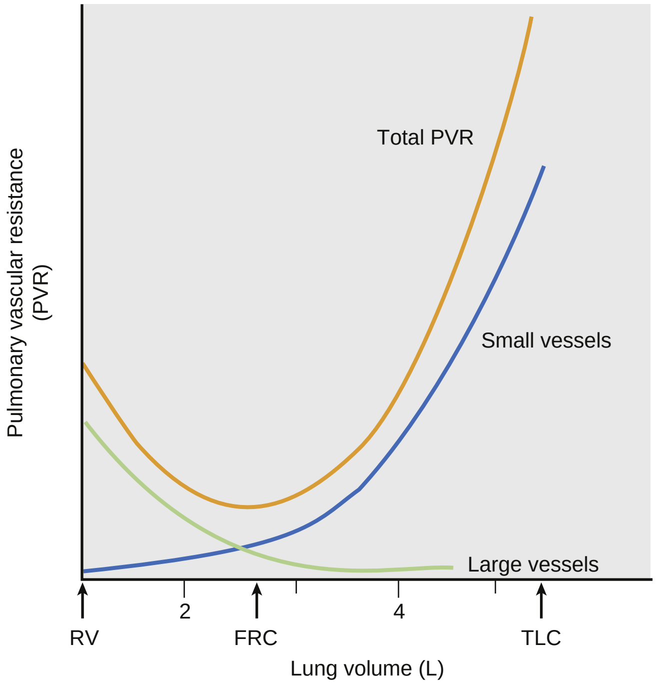

Fig. 53.31 The relationship between pulmonary vascular resistance *(PVR)* and lung volume. PVR is lowest at functional residual capacity *(FRC)* and increases as the lung volume decreases toward residual volume *(RV)*, caused primarily by an increase in the resistance of large pulmonary vessels. PVR also increases as lung volume increases above FRC toward total lung capacity *(TLC)* as a result of an increase in the resistance of small interalveolar lung vessels.

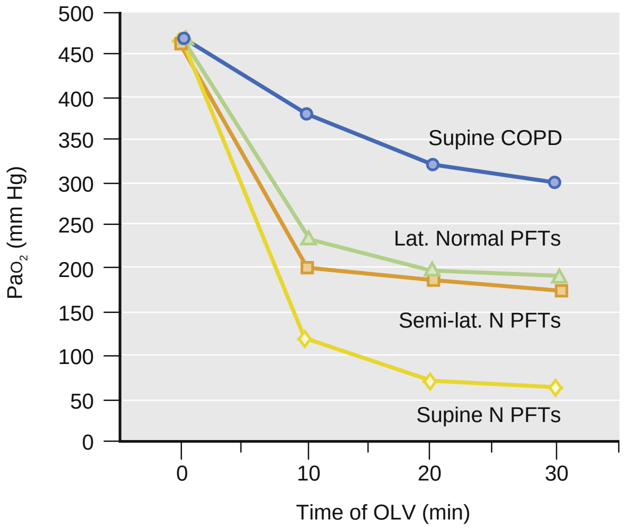

Fig. 53.32 Mean PaO$_2$ in groups of patients versus time of one-lung ventilation *(OLV)*. Supine chronic obstructive pulmonary disease (COPD) = patients with COPD having OLV in the supine position. Lat. Normal PFTs = patients with normal pulmonary function having OLV in the lateral position. Semi-lat. N PFTs = patients with normal pulmonary function having OLV in the semilateral position. Supine N PFTs = patients with normal pulmonary function having OLV in the supine position. Patients with normal pulmonary function having OLV in the supine position are the most likely to desaturate. (Based on data from Watanabe S, et al. *Anesth Anal*. 2000;90:28; and Bardoczy G, et al. *Anesth Analg*. 2008;90:35.)

and these are under the control of the anesthesiologist to a variable degree. These factors are illustrated in Fig. 53.30. The anesthesiologist's goal during OLV is to maximize PVR in the nonventilated lung while minimizing PVR in the ventilated lung. Key to understanding this physiology is the appreciation that PVR is correlated with lung volume in a hyperbolic fashion (Fig. 53.31). PVR is lowest at FRC and increases as lung volume rises or falls above or below FRC.[147] The anesthesiologist's aim, to optimize pulmonary blood flow redistribution during OLV, is to maintain the ventilated lung as close as possible to its FRC while facilitating collapse of the nonventilated lung to increase its PVR.

INTRAOPERATIVE POSITION

Most thoracic surgery is performed in the lateral position. Patients having OLV in the lateral position have significantly better PaO$_2$ levels than patients during OLV in the supine position.[148] This applies both to patients with normal lung function and to those with COPD (Fig. 53.32).[149]

Hypoxic Pulmonary Vasoconstriction

HPV is thought to be able to decrease the blood flow to the nonventilated lung by 50%.[150] The stimulus for HPV is primarily the PAO$_2$, which stimulates precapillary vasoconstriction, redistributing pulmonary blood flow away from hypoxemic lung regions via a pathway involving NO and/or cyclooxygenase (COX) synthesis inhibition.[151] The mixed venous PO$_2$ (P_vO_2) is also a stimulus although considerably weaker than PAO$_2$. HPV has a biphasic temporal response

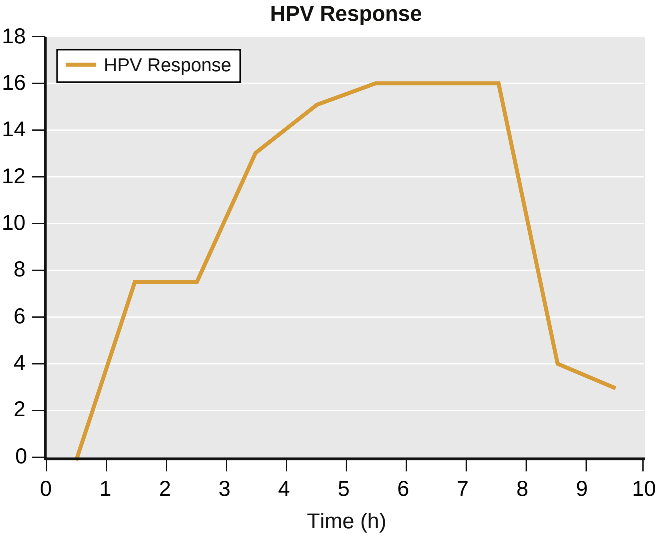

Fig. 53.33 The relationship between hypoxic pulmonary vasoconstriction *(HPV)* (vertical axis) and time in hours (h) (horizontal axis) in humans exposed to isocapnic hypoxia (approximate inspired PO_2 60 mm Hg) beginning at baseline with a return to normoxia at 8 hours. HPV response was measured as the increase in echocardiographic right ventricular systolic pressure. Note the two-phase, rapid and slow, onset of HPV. Also note that after prolonged HPV, the pulmonary pressures do not return to baseline for several hours. (Based on data from Talbot, et al. *J Appl Physiol*. 2005;98:1125.)

to alveolar hypoxia. The rapid-onset phase begins immediately and reaches a plateau by 20 to 30 minutes. The second (delayed) phase begins after 40 minutes and plateaus after 2 hours (Fig. 53.33).[152] The offset of HPV is also biphasic and PVR may not return to baseline for several hours after a prolonged period of OLV. This may contribute to increased desaturation during the collapse of the second lung during bilateral thoracic procedures. HPV is also a reflex that has a preconditioning effect and the response to a second hypoxic challenge will be greater than to the first challenge.[153]

The surgical trauma to the lung can affect pulmonary blood flow redistribution. Surgery may oppose HPV by release of vasoactive metabolites locally in the lung. Conversely, surgery can dramatically decrease blood flow to the nonventilated lung by deliberately or accidentally mechanically interfering with either the unilateral pulmonary arterial or venous blood flow.[154] Ventilation increases blood flow through a hypoxic lung more than in a normoxic lung, which is generally not of clinical relevance but does complicate studies of HPV. HPV is decreased by vasodilators such as nitroglycerin and nitroprusside. In general, vasodilators can be expected to cause a deterioration in P_aO_2 during OLV. Thoracic epidural sympathetic blockade probably has little or no direct effect on HPV, which is a localized chemical response in the lung.[155] However thoracic epidural anesthesia can have an indirect effect on oxygenation during OLV if it is allowed to cause hypotension and a fall in cardiac output (see "Cardiac Output" later).

CHOICE OF ANESTHETIC

All of the volatile anesthetics inhibit HPV in a dose-dependent fashion. Animal studies suggest that this inhibition is dependent on the agent: halothane > enflurane > isoflurane.[156] The older anesthetics were potent inhibitors of HPV and this may have contributed to the high incidence of hypoxemia reported during OLV in the 1960s and 1970s (see earlier); many of these studies used 2- to 3-minimum alveolar concentration (MAC) doses of halothane.

In doses of less than or equal to 1 MAC, the modern volatile anesthetics (isoflurane, sevoflurane,[157] and desflurane[158]) are weak, and equipotent, inhibitors of HPV. The inhibition of the HPV response by 1 MAC of a volatile anesthetic such as isoflurane is approximately 20% of the total HPV response, and this could account for only a net 4% increase in total arteriovenous shunt during OLV, which is a difference too small to be detected in most clinical studies.[159] In addition, volatile anesthetics cause less inhibition of HPV when delivered to the active site of vasoconstriction via the pulmonary arterial blood than via the alveolus. This pattern is similar to the HPV stimulus characteristics of oxygen. During established OLV, the volatile agent only reaches the hypoxic lung pulmonary capillaries via the mixed venous blood. No clinical benefit in oxygenation during OLV has been shown for total intravenous anesthesia above that seen with 1 MAC of the modern volatile anesthetics.[160]

The use of N_2O/O_2 mixtures is associated with a higher incidence of postthoracotomy radiographic atelectasis (51%) in the dependent lung than when air/oxygen mixtures are used (24%). N_2O also tends to increase pulmonary artery pressures in patients who have pulmonary hypertension and N_2O inhibits HPV. For these reasons N_2O is usually avoided during thoracic anesthesia.

Volatile anesthetic techniques seem to be associated with less release of proinflammatory cytokines and possibly fewer postoperative pulmonary complications following OLV compared to intravenous anesthetics. In a randomized study comparing sevoflurane to propofol for anesthesia in pulmonary resection, the sevoflurane group had significantly fewer postoperative pulmonary complications (14% vs. 28%) and lower 1-year mortality (2.3% vs. 12.5%).[161]

CARDIAC OUTPUT

The effects of alterations of cardiac output during OLV are complex (Fig. 53.34). Increasing cardiac output tends to cause increased pulmonary artery pressures and passive dilation of the pulmonary vascular bed, which in turn opposes HPV and has been shown to be associated with increased arteriovenous shunt (Qs/Qt) during OLV.[162] However, in patients with a relatively fixed oxygen consumption, as is seen during stable anesthesia, the effect of an increase in cardiac output is to increase the S_VO_2. Thus increasing cardiac output during OLV tends to increase both shunt and S_VO_2, which have opposing effects on P_aO_2. There is a ceiling effect to the amount that S_VO_2 can be increased. Increasing the cardiac output to supranormal levels by administering inotropes, such as dopamine, tends to have an overall negative effect on PaO_2.[163] Conversely, allowing the cardiac output to fall will lead to falls in both shunt and S_VO_2 with a net effect of decreasing PaO_2. Because even with optimal anesthetic management there is usually a shunt of 20% to 30% during OLV, it is very important to maintain cardiac output.

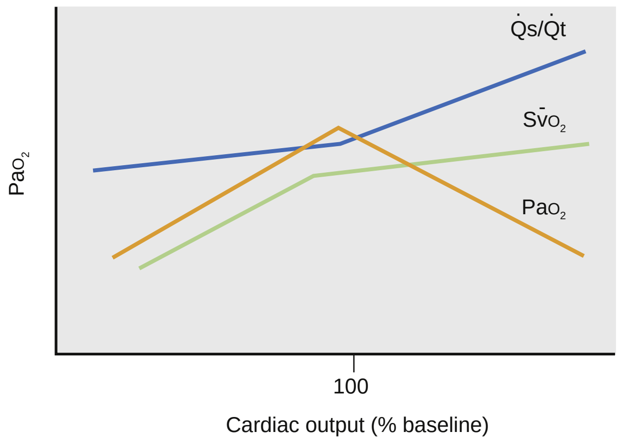

Fig. 53.34 The relationship between PaO_2 and cardiac output during OLV. As cardiac output falls below baseline, arteriovenous shunt (Qs/Qt) falls, but the mixed venous oxygen saturation (SvO_2) also decreases, resulting in a net fall in PaO_2. Conversely, raising cardiac output above baseline tends to increase SvO_2 but also increase Qs/Qt and the net result again is a decrease in PaO_2. *OLV*, One-lung ventilation. (Based on data from Slinger P, Scott W. *Anesthesiology*. 1995;82:940, and Russell W, James M. *Anaesth Intens Care*. 2004;32:644.)

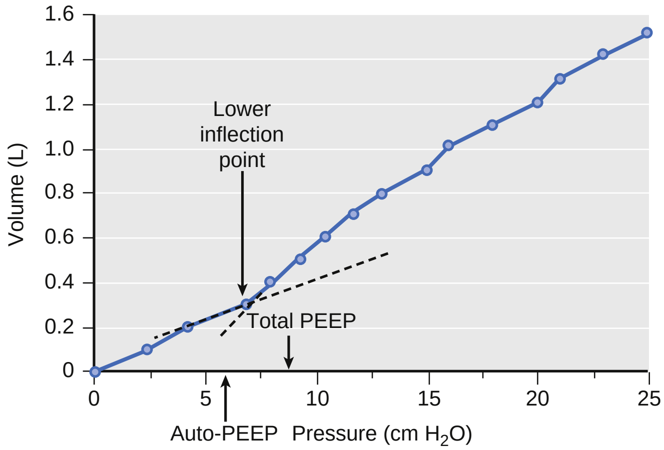

Fig. 53.35 The static compliance curve of the ventilated (dependent) lung in a typical lung cancer patient with mild COPD. The Lower Inflection Point is thought to represent functional residual capacity. This patient had 6 cm H_2O of auto-PEEP during OLV. Adding 5 cm H_2O PEEP to the ventilator resulted in a total PEEP in the circuit of 9 cm H_2O. This patient had a decrease in PaO_2 with the addition of PEEP. *auto-PEEP*, Occult positive end-expiratory pressure; *COPD*, chronic obstructive pulmonary disease; *PEEP*, positive end-expiratory pressure. (Based on data from Slinger P, et al. *Anesthesiology*. 2001;95:1096.)

Ventilation Strategies During One-Lung Ventilation

The strategy used to manage the ventilated lung during OLV plays an important part in the distribution of pulmonary blood flow between the lungs. It has been the practice of many anesthesiologists to use the same large tidal volume (e.g., 10 mL/kg ideal body weight) during OLV as during TLV. This strategy probably decreases hypoxemia by recurrently recruiting atelectatic regions in the dependent lung and may result in higher PaO_2 values during OLV than compared to smaller tidal volumes.[164] However, there is a trend to use smaller tidal volumes with PEEP during OLV for several reasons. First, the incidence of hypoxemia during OLV is much lower than 20 to 30 years ago. Second, there is a risk of causing acute injury to the ventilated lung with prolonged use of large tidal volumes. And third, a ventilation pattern that allows recurrent atelectasis and recruitment of lung parenchyma seems to be injurious.[165] The ventilation technique needs to be individualized depending on the patient's underlying lung mechanics.

RESPIRATORY ACID-BASE STATUS

The efficacy of HPV in a hypoxic lung region is increased in the presence of respiratory acidosis and is inhibited by respiratory alkalosis. However, there is no net benefit to gas exchange during OLV from hypoventilation because the respiratory acidosis preferentially increases the pulmonary vascular tone of the well-oxygenated lung and this opposes any clinically useful pulmonary blood flow redistribution.[166] Overall, the effects of hyperventilation will usually tend to decrease pulmonary vascular pressures.

POSITIVE END-EXPIRATORY PRESSURE

Resistance to blood flow through the lung is related to lung volume in a biphasic pattern and is lowest when the lung is at its FRC. Keeping the ventilated lung as close as possible to its normal FRC favorably encourages pulmonary blood flow to this lung. Several intraoperative factors known to alter FRC tend to cause the FRC of the ventilated lung to fall below its normal level; these include lateral position, paralysis, and opening the nondependent hemithorax, which allows the weight of the mediastinum to compress the dependent lung. Attempts to measure FRC in human patients during OLV have been complicated by the presence of a persistent end-expiratory airflow in COPD patients.[167] Many patients do not actually reach their end-expiratory equilibrium FRC lung volume as they try to exhale a relatively large tidal volume through one lumen of a DLT. These patients develop dynamic hyperinflation and an occult positive end-expiratory pressure (auto-PEEP).[61]

Auto-PEEP occurs in patients with decreased lung elastic recoil, such as the elderly or those with emphysema.[168] Auto-PEEP increases as the inspiratory/expiratory (I:E) ratio increases (i.e., as the time of expiration decreases). This auto-PEEP, which averages 4 to 6 cm H_2O in most series of lung cancer patients with COPD, opposes the previously mentioned factors, which tend to diminish dependent-lung FRC during OLV. The effects of applying external PEEP through the ventilator circuit to the lung in the presence of auto-PEEP are complex (Fig. 53.35). Patients with low auto-PEEP (<2 cm H_2O) will experience a greater increase in total PEEP from a moderate (5 cm H_2O) external PEEP than those with a high level of auto PEEP (>10 cm H_2O). Whether the application of PEEP during OLV will improve a patient's gas exchange depends on the individual's lung mechanics. If the application of PEEP tends to shift the expiratory equilibration position on the compliance curve toward the lower inflection point (LIP) of the curve (i.e., toward the FRC) then external PEEP is of benefit (Fig. 53.36). However, if the application of PEEP raises the equilibration point such that it is further from the LIP, then gas exchange deteriorates.

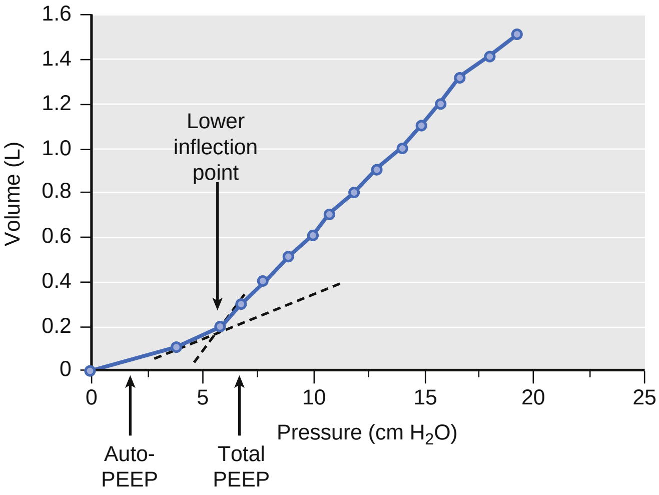

Fig. 53.36 Static compliance curve of a young patient with normal pulmonary function during OLV (in this case for removal of a mediastinal tumor). The Lower Inflection Point of the curve (functional residual capacity) was at 6 cm H_2O. The patient had 2 cm H_2O auto-PEEP during OLV. Adding 5 cm H_2O PEEP to the ventilator raised the total PEEP to 7 cm H_2O and improved PaO_2. Patients with normal lung mechanics and patients with increased lung elastic recoil (such as caused by restrictive lung diseases) have an increase in PaO_2 from PEEP during OLV. *auto-PEEP*, occult positive end-expiratory pressure; *OLV*, One-lung ventilation; *PEEP*, positive end-expiratory pressure. (Based on data from Slinger P, et al. *Anesthesiology*. 2001;95:1096.)

Auto-PEEP is difficult to detect and measure using currently available anesthetic ventilators. To detect auto-PEEP the respiratory circuit must be held closed at the end of a normal expiration until an equilibrium appears in the airway pressure.[169] Most current intensive care ventilators can be used to measure auto-PEEP.

TIDAL VOLUME

There will be an optimal combination of tidal volume, respiratory rate, I:E ratio, and pressure- or volume-control ventilation for each individual patient during OLV. However, to try to assess each of these parameters while still providing anesthesia with the available anesthetic ventilators is not practical, and the clinician must initially rely on a simplified strategy (Table 53.9). The results of alterations in tidal volume are unpredictable. This may be caused partly by the interaction of tidal volume with auto-PEEP. The use of 5 to 6 mL/kg ideal body weight tidal volumes plus 5 cm H_2O PEEP initially for most patients (except those with COPD) seems a logical starting point during OLV.[170] Tidal volume should be managed so that peak airway pressures do not exceed 35 cm H_2O. This will correspond to a plateau airway pressure of approximately 25 cm H_2O.[171] Peak airway pressures exceeding 40 cm H_2O may contribute to hyperinflation injury of the ventilated lung during OLV.[172]

Turning the patient to the lateral position will increase respiratory dead space and the arterial to end-tidal CO_2 tension gradient ($P_{a\text{-}ET}CO_2$). This will usually require a 20% increase in minute ventilation to maintain the same P_aCO_2. Individual variations in $P_{a\text{-}ET}CO_2$ gradient become much larger, and $P_{ET}CO_2$ is less reliable as a monitor of P_aCO_2 during OLV. This effect is possibly because there are individual differences in the excretion of CO_2 between the dependent and nondependent lungs.

TABLE 53.9 Suggested Ventilation Parameters for One-Lung Ventilation

Parameter	Suggested	Guidelines/Exceptions
1. Tidal volume	5–6 mL/kg ideal body weight	Maintain: Peak airway pressure <35 cm H_2O Plateau airway pressure <25 cm H_2O
2. Positive end-expiratory pressure	5–10 cm H_2O	Patients with COPD, no added PEEP
3. Respiratory rate	12 breaths/min	Maintain normal $PaCO_2$, Pa-et CO_2 will usually increase 1–3 mm Hg during OLV
4. Mode	Pressure-controlled or volume-controlled	Pressure-control for patients at risk of lung injury (e.g., bullae, pneumonectomy, postlung transplantation)

COPD, Chronic obstructive pulmonary disease; *OLV*, one-lung ventilation; *PEEP*, positive end-expiratory pressure.

VOLUME-CONTROL VERSUS PRESSURE-CONTROL VENTILATION

Pressure-control ventilation has not been shown to improve oxygenation versus volume-control ventilation for most patients, although the peak airway pressures are lower.[173] The decrease in peak pressure with pressure-control ventilation may be largely in the anesthetic circuit and not at the distal airway.[174] Pressure-control ventilation will avoid sudden increases in peak airway pressures that may result from surgical manipulation in the chest. This will be of benefit when a bronchial blocker is used and in patients at increased risk for lung injury from high pressures such as after lung transplantation or during a pneumonectomy.[175] Because of the rapid changes of lung compliance that occur during pulmonary surgery, when pressure-control ventilation is used the delivered tidal volume needs to be closely monitored as this may change suddenly.

Prediction of Hypoxemia During One-Lung Ventilation

The problem of hypoxemia during OLV has prompted much research in thoracic anesthesia. Hypoxemia during OLV is predictable (see Box 53.7), preventable, and treatable in the vast majority of cases.[176]

PREOPERATIVE VENTILATION-PERFUSION SCAN

The shunt and P_aO_2 during intraoperative OLV are highly correlated with the fractional perfusion of the ventilated lung as determined by a preoperative ventilation/perfusion scan.[177] Patients with long-standing unilateral disease on the operative side develop a unilateral decrease of ventilation and perfusion and tolerate OLV very well. Similarly, patients who intraoperatively have a higher proportion of gas exchange in the dependent lung during OLV tend to have better oxygenation during OLV.

SIDE OF OPERATION

Patients having right-sided thoracotomies tend to have a larger shunt and lower P_aO_2 during OLV because the right lung is larger and normally 10% better perused than the left. The overall mean P_aO_2 difference between left and right thoracotomies during stable OLV is approximately 100 mm Hg.[178]

TWO-LUNG OXYGENATION

Patients who have better P_aO_2 levels during TLV in the lateral position tend to have better oxygenation during OLV. These patients may have better abilities to match ventilation and perfusion (individual variability of HPV response) and/or they may have less atelectasis in the dependent lung. This is a particularly relevant consideration in trauma patients who may require a thoracotomy but have a contusion of the dependent lung.

PREOPERATIVE SPIROMETRY

Studies consistently show that when the aforementioned factors are controlled, patients with better spirometric lung function preoperatively are more likely to desaturate and have lower P_aO_2 values during OLV. Clinically this is evident because emphysematous lung-volume reduction patients generally tolerate OLV very well. The explanation is not clear but may be related to maintenance of a more favorable FRC in patients with obstructive airways' disease during OLV with an open hemithorax due to the development of auto-PEEP.[64]

Treatment of Hypoxemia During One-Lung Ventilation

During OLV there will be a fall in arterial oxygenation that usually reaches its nadir 20 to 30 minutes after the initiation of OLV then the saturation will stabilize or may rise slightly as HPV increases over the next 2 hours. The majority of patients who desaturate do so quickly and within the first 10 minutes of OLV. Hypoxemia during OLV responds readily to treatment in the vast majority of cases. Potential therapies are outlined in Box 53.12.

BOX 53.12 **Therapies for Desaturation during One-Lung Ventilation**

- **Severe or precipitous desaturation:** resume two-lung ventilation (if possible)
- **Gradual desaturation:**
  - Ensure that delivered FiO_2 is 1.0
  - Check position of double-lumen tube or blocker with fiberoptic bronchoscopy
  - Ensure that cardiac output is optimal, decrease volatile anesthetics to <1 MAC
  - Apply a recruitment maneuver to the ventilated lung (this will transiently make the hypoxemia worse)
  - Increase PEEP to the ventilated lung (except in patients with emphysematous pathology)
  - Apneic oxygen insufflation of the nonventilated lung
  - Apply CPAP 1–2 cm H_2O to the nonventilated lung (apply a recruitment maneuver to this lung immediately before CPAP)
  - Partial ventilation techniques of the nonventilated lung
    - Intermittent positive pressure ventilation
    - Fiberoptic lobar insufflation
    - Selective lobar collapse (using a bronchial blocker)
    - Small tidal volume ventilation
  - Pharmacologic manipulations (see text)
  - Mechanical restriction of the blood flow to the nonventilated lung (if possible)
  - Venovenous ECMO

CPAP, Continuous positive airway pressure; *ECMO*, extracorporeal membrane oxygenation; *MAC*, minimum alveolar concentration; *PEEP*, positive end-expiratory

1. Resume two-lung ventilation. Reinflate the nonventilated lung and deflate the bronchial cuff of the DLT or the bronchial blocker. This will necessitate interruption of surgery but is necessary in case of severe or precipitate desaturation. After an adequate level of oxygenation is obtained, the diagnosis of the cause of desaturation can be made and prophylactic measures instituted (see later) before another trial of OLV is attempted.
2. Increase FiO_2. Ensure that the delivered FiO_2 is 1.0. This is an option in essentially all patients except those who have received bleomycin or similar therapies that potentiate pulmonary oxygen toxicity.
3. Recheck the position of the DLT or bronchial blocker. Ensure that there is no lobar obstruction in the ventilated lung.
4. Check the patient's hemodynamics to ensure that there has been no decrease in cardiac output. It is very common for the surgeon to accidentally compress the inferior vena cava during pulmonary resections and the fall in blood pressure and cardiac output that this causes leads to rapid desaturation during OLV. Treat the fall in cardiac output as indicated (e.g., inotropes/vasopressors if due to thoracic epidural sympathetic blockade). Stop administration of vasodilators, decrease MAC of volatile anesthetics to less than or equal to 1 MAC.
5. Perform a recruitment maneuver of the ventilated lung. To eliminate any atelectasis inflate the lung to 20 cm H_2O or more for 15 to 20 seconds. This may cause transient hypotension and will also cause a transient further fall in the PaO_2 as the blood flow is temporarily redistributed to the nonventilated lung.
6. Apply PEEP to the ventilated lung. It is necessary to perform a recruitment maneuver before applying PEEP to get the maximal benefit. PEEP will raise the end-expiratory volume of the ventilated lung toward the FRC in patients with normal lung mechanics and in those with increased elastic recoil caused by restrictive disease. It is not possible to predict the optimal PEEP for individual patients. It is useful to titrate PEEP between 5 to 10 cm H_2O to maximize compliance while maintaining a driving pressure (plateau pressure-PEEP) of 15 cm H_2O or less.[179] PEEP will increase the end-expiratory lung volume of patients with significant levels of auto-PEEP (e.g., emphysema patients). Unlike CPAP, application of PEEP does not require reinflation of the nonventilated lung and interruption of surgery. PEEP has been shown to be as effective for increasing PaO_2 levels during OLV in patients with normal lung function as CPAP

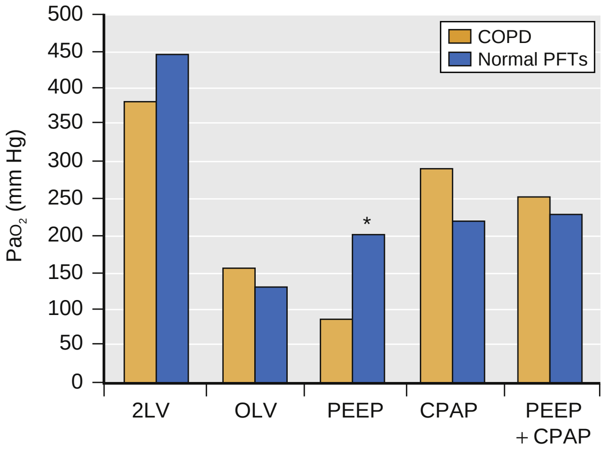

Fig. 53.37 A comparison of the effects of positive end-expiratory pressure *(PEEP)* to the ventilated lung and continuous positive airway pressure *(CPAP)* to the nonventilated lung on mean PaO_2 levels during one-lung ventilation *(OLV)*. *2LV*, Two-lung ventilation; *COPD*, a group of lung cancer surgery patients; *Normal PFTs*, a group of esophageal surgery patients with normal preoperative pulmonary function tests. *Significance of $P < .05$ versus OLV. (Based on data from Fujiwara M, et al. *J Clin Anesth*. 2001;13:473; and Capan L, et al. *Anesth Analg*. 1980;59:847.)

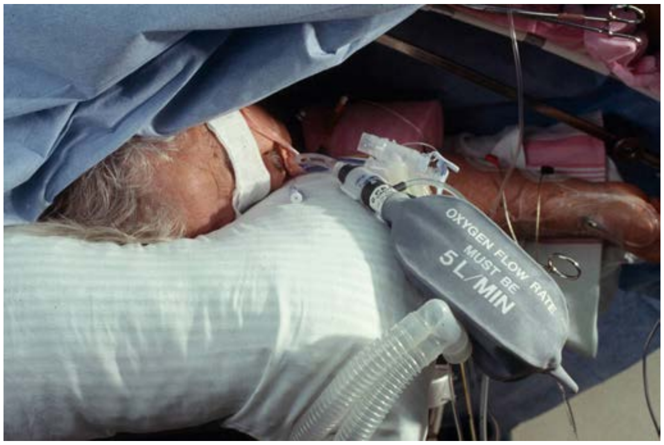

Fig. 53.38 Photograph of a commercial (Mallinckrodt, St. Louis, MO) disposable CPAP circuit applied to the nonventilated lung during a left thoracotomy (in this case applied to the tracheal lumen of a right-sided DLT). This circuit has an adjustable exhaust valve that allows titration of CPAP between 1 and 10 cm H_2O. *CPAP*, Continuous positive airway pressure; *DLT*, double-lumen endobronchial tube.

(Fig. 53.37).[180] For patients with normal pulmonary function it is logical to routinely apply a recruitment maneuver and PEEP from the start of OLV.

7. Apneic oxygen insufflation to the nondependent lung. Application of 3 liters of O_2, via a suction catheter to the nonventilated lumen of the DLT, improved PaO_2 during OLV without interference to the surgical field.[181]
8. CPAP with oxygen to the nonventilated lung is a reliable method to improve PaO_2 during OLV.[182] CPAP should be applied to an inflated (recruited) lung to be completely effective. The opening pressure of atelectatic lung regions is greater than 20 cm H_2O[183] and these units will not be recruited by simple application of CPAP levels of 5 to 10 cm H_2O.[184] When CPAP is applied to an inflated lung, levels of CPAP as low as 1 to 2 cm H_2O can be used.[185] Since the normal transpulmonary pressure of the lung at FRC is approximately 5 cm H_2O, levels of 5 to 10 cm H_2O CPAP applied to a fully recruited lung result in a large-volume lung that impedes surgery particularly during minimally invasive procedures. Lower FiO_2 levels of CPAP are of clinical benefit and can be titrated to the ventilated lung in patients at risk of oxygen toxicity using an air/oxygen blender.

   Numerous anesthetic systems to apply CPAP to the nonventilated lung have been described. Essentially all that is required is a CPAP (or PEEP) valve and an oxygen source. Ideally the circuit should permit variation of the CPAP level and include a reservoir bag to allow easy reinflation of the nonventilated lung and a manometer to measure the actual CPAP supplied. Such circuits are commercially available (Fig. 53.38) or can be readily constructed from standard anesthetic equipment.

   CPAP, even when properly administered, is not completely reliable to improve oxygenation during OLV. When the bronchus of the operative lung is obstructed, or open to atmosphere (as in a bronchopleural fistula or during endobronchial surgery), CPAP will not improve oxygenation. Also in certain situations, particularly during thoracoscopic surgery where access to the operative hemithorax is limited, CPAP can significantly interfere with surgery.[186]
9. Use of extracorporeal membrane oxygenation (ECMO). There have been multiple case reports of ECMO being used to manage thoracic surgery where oxygenation cannot be maintained with conventional techniques. The safety of venovenous ECMO makes it an option in some cases of complex lung surgery.[187]

PHARMACOLOGIC MANIPULATIONS

Eliminating known potent vasodilators such as nitroglycerin, halothane, and large doses of other volatile anesthetics will improve oxygenation during OLV.[188] The combination of NO and other pulmonary vasoconstrictors such as phenylephrine has been shown to improve oxygenation in ventilated intensive care unit patients with adult respiratory distress syndrome[189] and this may have applications in OLV. Systemic administration of a vasoconstrictor, to enhance pulmonary vasoconstriction, with simultaneous administration of an inhaled pulmonary vasodilator to the ventilated lung may improve hypoxemia in some cases of desaturation during OLV. This has been reported with the combination of intravenous phenylephrine and inhaled epoprostenol (Flolan).[190] A caveat is that the glycine diluent for nebulized epoprostenol tends to build up in the heat-moisture exchange (HME) filter of an anesthetic circuit causing increased airflow resistance. The HME filter should be changed every hour when nebulized epoprostenol is used.

Another drug that has been used is dexmedetomidine, a selective α-2 adrenoreceptor agonist. One study has shown that a continuous infusion of dexmedetomidine during OLV with sevoflurane anesthesia improved oxygenation and increased the PaO_2/FiO_2 ratio during the intraoperative period.[191] A subsequent meta-analysis reported that the use of dexmedetomidine improved the oxygenation index (assessment of intrapulmonary shunt and mean airway pressure) by improving oxygenation and decreasing intrapulmonary shunt fraction during OLV in patients receiving

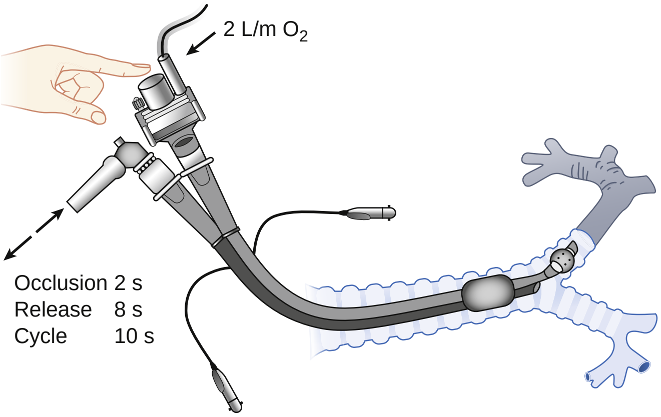

Fig. 53.39 A simple device to provide intermittent positive airway pressure to the nonventilated lung. A standard bacteriostatic filter is attached the lumen of the double-lumen tube to the nonventilated lung and an oxygen source is connected to the CO_2 sampling port of the filter. Intermittent manual occlusion of the open filter end improves oxygenation with minimal impact on surgical exposure (see text for details). (Reproduced with permission from Slinger P. *Principles and Practice of Anesthesia for Thoracic Surgery*. New York: Springer; 2011.)

intravenous and or inhalational agents.[192] One potential explanation for the effects of dexmedetomidine is that it reduces the required doses of inhalational anesthetics, thus reducing their potential negative effects on HPV.

INTERMITTENT REINFLATION OF THE NONVENTILATED LUNG

HPV becomes more effective during repeated hypoxic exposure. Often after reinflation, the oxygen saturation will be more acceptable during a second period of lung collapse. Reexpansion can be performed by regular reinflation of the operative lung via an attached CPAP circuit.

PARTIAL VENTILATION METHODS

Several alternative methods of OLV, all involving partial ventilation of the nonventilated lung, have been described and improve oxygenation during OLV. These techniques are useful in patients who are particularly at risk of desaturation such as those who have had previous pulmonary resections of the contralateral lung. These alternatives include:

1. Intermittent positive airway pressure to the nonventilated lung. This can be performed by a variety of methods. Russell described attaching a standard bacteriostatic filter to the nonventilated lumen of the DLT with a 2-L oxygen inflow attached to the CO_2 port of the filter (Fig. 53.39).[193] Manual occlusion of the filter for 2 seconds gives an insufflation of approximately 66 mL of oxygen to the nonventilated lung. This could be repeated at 10 second intervals with minimal interference with surgical exposure.
2. Selective insufflation of oxygen to recruit lung segments on the side of surgery but remote from the site of surgery (Fig. 53.40).[194] A useful technique in minimally invasive surgery is intermittent insufflation of oxygen using a fiberoptic bronchoscope. A 5-L oxygen flow is attached to the suction port of a fiberoptic bronchoscope that is passed under direct vision into a segment of the lung remote from the site of surgery, which is then reinflated by triggering the suction on the fiberoptic bronchoscope. The surgeon aids this technique by observing the lung inflation with the videoscope to avoid overdistention of the recruited segment(s).
3. Selective lobar collapse of only the operative lobe in the open hemithorax.[195] This is accomplished by placement of a blocker in the appropriate lobar bronchus of the ipsilateral operative lung while continuing to ventilate the other lobe(s) of the lung.
4. Ventilation of the operative (nondependent lung) with a small tidal volume via another ventilator connected to a limb of a DLT to the nondependent lung. A brief period of intermittent positive pressure ventilation to the nondependent lung with a small tidal volume (e.g., 70 mL) and respiratory rate of 6/min was effective in improving PaO_2 and SpO_2 during OLV without interference with the surgery.[196]

MECHANICAL RESTRICTION OF PULMONARY BLOOD FLOW

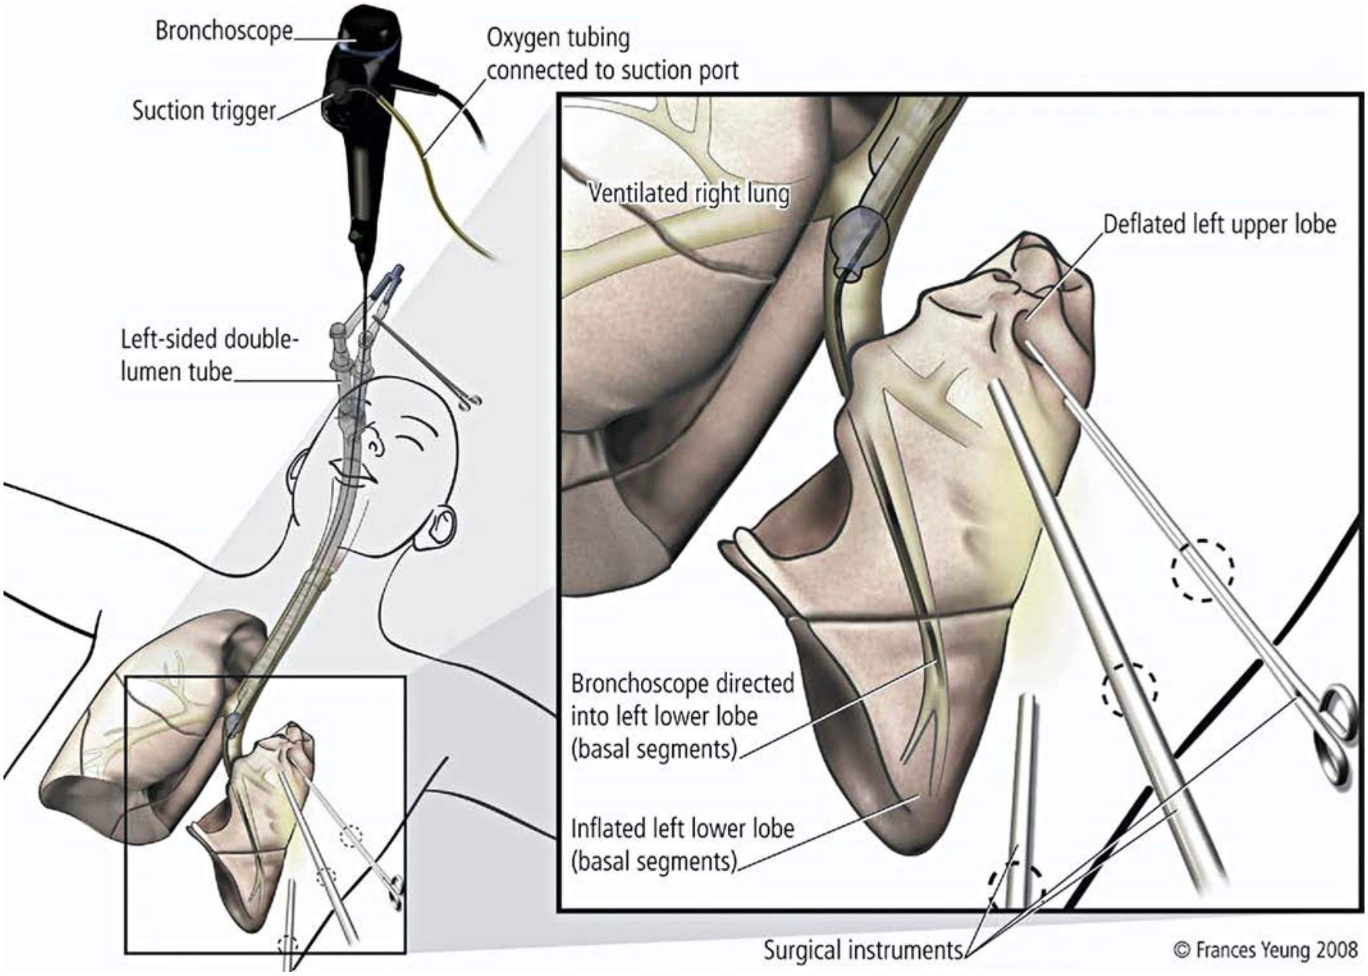
It is possible for the surgeon to directly compress or clamp the blood flow to the nonventilated lung.[197] This can be done temporarily in emergency desaturation situations or definitively in cases of pneumonectomy or lung transplantation. Another technique of mechanical limitation of blood flow to the nonventilated lung is the inflation of a pulmonary artery catheter balloon in the main pulmonary artery of the operative lung. The pulmonary artery catheter can be positioned at induction with fluoroscopic guidance and inflated as needed intraoperatively. This has been shown to be a useful technique for resection of large pulmonary arteriovenous fistulae.[198]

HYPOXEMIA PROPHYLAXIS

The majority of the treatments outlined as therapies for hypoxemia can be used prophylactically to prevent hypoxemia in patients who are at high risk of desaturation during OLV. The advantage of prophylactic therapy of hypoxemia, in addition to the obvious patient safety benefit, is that maneuvers involving CPAP or alternative ventilation patterns of the operative lung can be instituted at the onset of OLV in a controlled fashion and will not require interruption of surgery and emergent reinflation of the nonventilated lung at a time that may be extremely disadvantageous.

BILATERAL PULMONARY SURGERY

Because of mechanical trauma to the operative lung, the gas exchange in this lung will always be temporarily impaired after OLV. Also HPV offset may be delayed after reinflation of the first lung collapsed. Desaturation during bilateral lung procedures is particularly a problem during the second period of OLV (i.e., during OLV of the lung that has already had surgery).[199] Thus for bilateral procedures it is advisable to operate first on the lung that has better gas exchange and less propensity to desaturate during OLV. For the majority of patients, this means operating on the right side first.



Bronchoscope
Suction trigger
Oxygen tubing connected to suction port
Left-sided double-lumen tube
Ventilated right lung
Deflated left upper lobe
Bronchoscope directed into left lower lobe (basal segments)
Inflated left lower lobe (basal segments)

Anesthetic Management for Common Surgical Procedures

FLEXIBLE FIBEROPTIC BRONCHOSCOPY

Flexible fiberoptic bronchoscopy is a diagnostic and therapeutic procedure of great value in the clinical practice of thoracic surgery and anesthesia. In many centers, it is common practice to perform flexible fiberoptic bronchoscopy prior to lung resections, to reconfirm the diagnosis (if a tumor compresses the airway), or to determine the invasion and obstruction of the distal airway (in relation to the extension of the bronchial resection).

Anesthetic Management

There are multiple techniques for flexible fiberoptic bronchoscopy. Options include awake versus general anesthesia and oral versus nasal approaches. Options for local anesthesia include: topical anesthesia via a nebulizer, handheld aerosol, or soaked pledgets; nerve blocks (laryngeal and/or glossopharyngeal nerves); direct administration of local anesthetic through the bronchoscope (spray-as-you-go technique),[200] with/without sedation/opioid; or antisialagogues. Options during general anesthesia include spontaneous versus positive-pressure ventilation with/without muscle relaxation. Airway management during general anesthesia can be with an ETT or a laryngeal mask airway (LMA). A Portex swivel connector with a self-sealing valve is used to facilitate the ventilation and manipulation of the bronchoscope; at the same time inhalation and/or intravenous agents can be used for anesthesia. Patients who have copious secretions in the preoperative period should receive anticholinergic medication to ensure a dry field, which provides optimal visualization with the flexible bronchoscope.

The advantages of an LMA technique include visualization of the vocal cords and subglottic structures as well as a lower airway resistance versus the ETT when the bronchoscope is inserted (Fig. 53.41). This is particularly useful in the patient with a difficult airway, when maintaining spontaneous respiration may be the safest method of anesthetic management.[201] Self-expanding flexometallic tracheal and bronchial stents can be placed with fiberoptic or rigid bronchoscopy (Fig. 53.42). However, Silastic airway stents require rigid bronchoscopy for placement.

RIGID BRONCHOSCOPY

Rigid bronchoscopy has traditionally been considered the technique of choice for the preoperative diagnostic assessment of an airway obstruction involving the trachea, and in the therapy of massive hemoptysis and foreign bodies in the airway. The role of interventional bronchoscopy with laser, bronchial dilation, or stent insertion is well established for the treatment of malignant and benign central airway and endobronchial lesions (Fig. 53.43).[202] Rigid bronchoscopy is the procedure of choice for operative procedures such as dilation of tracheal stenosis.

Anesthetic Management

Patients undergoing rigid bronchoscopy should have a complete preoperative evaluation including radiological studies. Chest radiographs and chest CT scans should be reviewed in the preoperative evaluation. If time permits, it is recommended that patients with severe stridor receive pharmacologic interventions for temporary stabilization of the condition. Treatments may include inspired cool saline mist, nebulized racemic epinephrine, and the use of systemic steroids.[203]

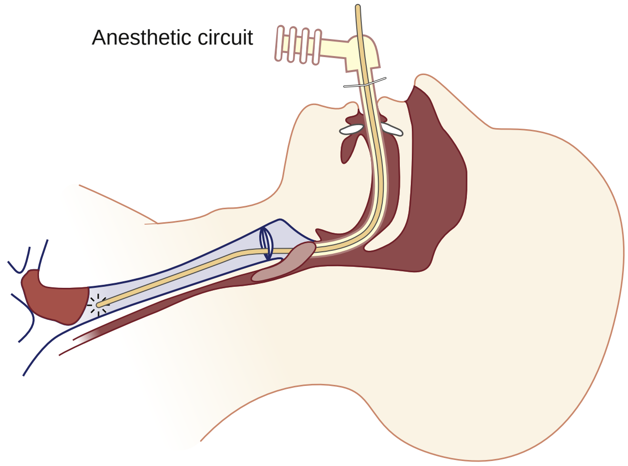

Fig. 53.41 Diagram of fiberoptic bronchoscopy performed via a laryngeal mask airway (LMA) during general anesthesia in a spontaneously breathing patient with a carinal tumor, in this case for diagnosis and Nd:YAG laser tumor excision. The LMA permits visualization of the vocal cords and subglottic structures with the bronchoscope, which is not possible when fiberoptic bronchoscopy is performed via an endotracheal tube.

There are four basic methods of ventilation management for rigid bronchoscopy:

1. Spontaneous ventilation. The addition of topical anesthesia or nerve blocks to the airway decreases the tendency to breath-hold and cough when volatile anesthetics are used.
2. Apneic oxygenation (with/without insufflation of oxygen). This requires thorough preoxygenation, and the anesthesiologist will have to interrupt surgery to ventilate the patient before desaturation occurs. This should allow the surgeon working intervals of 3 minutes. or longer depending on the underlying condition of the patient.
3. Positive-pressure ventilation via a ventilating bronchoscope (Fig. 53.44). This allows the use of a standard anesthetic circuit but may cause significant air leaks if there is a discrepancy between the size of a smaller bronchoscope and a larger airway.
4. Jet ventilation. This can be performed with a handheld injector such as the Sanders injector[204] or with a high-frequency ventilator. These techniques are most useful with intravenous anesthesia since they entrain gas from either the room air or an attached anesthetic circuit, and the dose of any volatile agent delivered will be very uncertain.

The use of anticholinergic agents (e.g., 0.2 mg intravenous glycopyrrolate) before manipulation of the airway will decrease secretions during the bronchoscopic examination. For a patient undergoing rigid bronchoscopy, the surgeon must be at the bedside for the induction of anesthesia and be prepared to establish airway control with the rigid bronchoscope. In children, anesthesia for rigid bronchoscopy is most commonly performed with spontaneous ventilation. In adults, intravenous anesthesia and the use of muscle relaxants is more common.

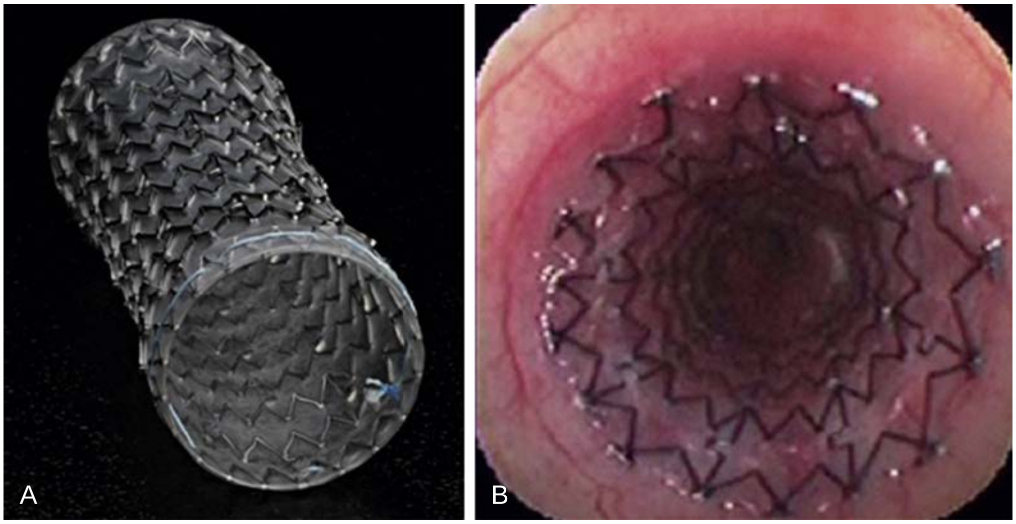

Fig. 53.42 (A) A self-expanding flexometallic airway stent. (B) Fiberoptic bronchoscopic view of the proximal end of a flexometallic tracheal stent.

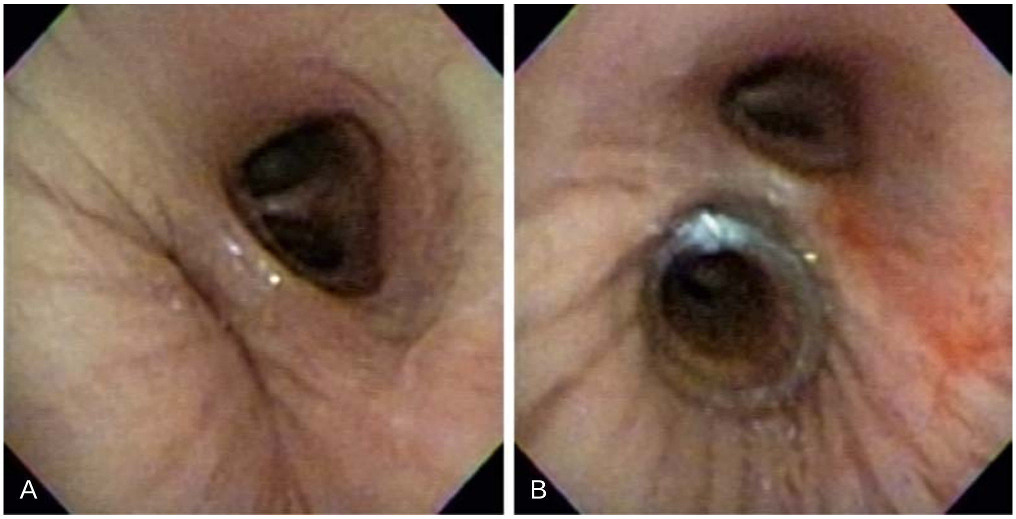

Fig. 53.43 (A) Photograph of a patient with a collapse of the left lower lobe bronchus post–lung transplantation. (B) A silastic stent has been placed in the left lower lobe bronchus with rigid bronchoscopy.

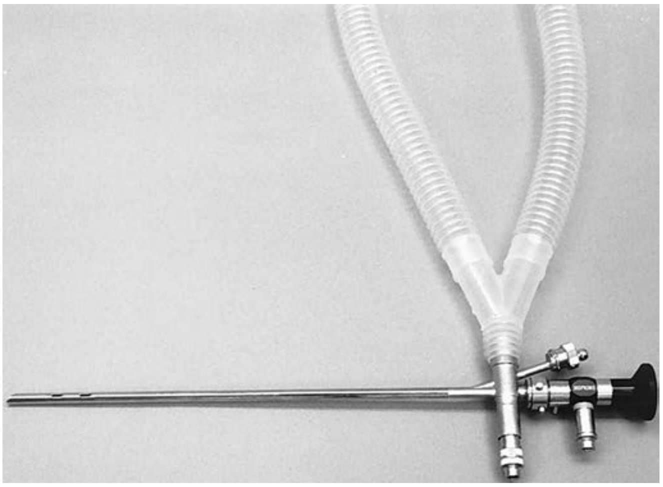

Fig. 53.44 Photograph of a ventilating rigid bronchoscope with an anesthetic circuit attached to the side arm. In this photograph there is a telescopic lens sealing the proximal end of the bronchoscope. (From Kaplan J, Slinger P, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

In cases for which the use of muscle relaxants is not contraindicated, a short-acting agent (succinylcholine) can be used initially to facilitate intubation with either a small SLT or the rigid bronchoscope. Nondepolarizing relaxants may be needed for prolonged procedures such as stent placement or tumor resection. Mouth guards should be used to protect the upper and lower teeth and gums from the pressure of the bronchoscope. Remifentanil and propofol infusions can be administered if an intravenous regimen is the planned anesthetic.[205] This is a useful technique if the surgeon needs repeated access (for suction or instrumentation) to the open airway since it maintains the level of anesthesia and avoids contaminating the operating room with exhaled anesthetic vapors.

For cases in which a neodymium-doped yttrium-aluminum-garnet (Nd:YAG) laser is used, the FiO_2 should be maintained in the lowest acceptable range (i.e., $<30\%$ if possible) according to patient oxygen saturation, to avoid the potential for fire in the airway. Since any common material (including porcelain and metal) can be perforated by the Nd:YAG laser it is best to avoid any potentially combustible substance in the airway when the Nd:YAG laser is used.[206] Because of its high energy and short wavelength, the Nd:YAG laser has several advantages for distal airway surgery over the CO_2-laser, which is used in upper airway surgery. The Nd:YAG laser penetrates tissue more deeply so it causes more coagulation in vascular tumors and it can be refracted and passed in fibers through a flexible or rigid bronchoscope. However, there is a higher potential for accidental reflected laser strikes and there is more delayed airway edema.

Rigid bronchoscopes have different sizes, commonly from 3.5- to 9-mm diameters, with a ventilating side port to facilitate ventilation when the bronchoscope is placed into the airway. If excessive leak of tidal volume occurs around the bronchoscope with positive-pressure ventilation, it may be necessary to place throat packs to facilitate ventilation. Continuous communication with the surgeon or pulmonologist is necessary in case desaturation occurs. If desaturation does occur it must be corrected by stopping surgery and allowing the anesthesiologist to ventilate and oxygenate the patient, either via the rigid bronchoscope or by removing the bronchoscope and ventilating with a mask, LMA, or ETT.

Pulse oximetry is vital during rigid bronchoscopy because there is a high risk of desaturation. There is no simple way to monitor end-tidal CO_2 or volatile anesthetics since the airway remains essentially open to atmosphere. For prolonged procedures, it is useful to perform repeated arterial blood gas analysis to confirm the adequacy of ventilation. An alternative is to interrupt surgery and ventilate the patient with a standard circuit and a mask or ETT to assess the end-tidal CO_2.

Unlike during fiberoptic bronchoscopy via an ETT, with rigid bronchoscopy the airway is never completely secure and there is always the potential for aspiration in patients at increased risk, such as those with a full stomach, hiatus hernia, morbid obesity, and so on. It is always best to defer rigid bronchoscopy to decrease the aspiration risk if possible in these patients. When there is no benefit to be gained by deferring and/or the airway risk is acute (e.g., aspiration of an obstructing foreign body), there is no simple solution and each case will need to be managed on an individual basis depending on the context and considering the competing risks.

Other uses of the rigid bronchoscope that require anesthesia include: dilation for benign airway stenosis, coring-out of malignant lesions in the trachea, laser ablation of endobronchial and carinal tumors, and therapeutic bronchoscopic interventions before surgical resection of lung cancer. Additionally, interventional bronchoscopy is often used for the management of airway complications following lung transplantation.

Complications of rigid bronchoscopy include: airway perforation, mucosal damage, hemorrhage, postmanipulation airway edema, and potential airway loss at the end of the procedure. In some situations, it may be necessary to keep the patient intubated with a small (i.e., 6.0-mm ID) SLT after a rigid bronchoscopy if an edematous airway is suspected or if the patient is not able to be extubated. These patients may require the use of steroids, nebulized racemic epinephrine, or helium-oxygen mixtures to treat stridor in the postoperative period.

MEDIASTINOSCOPY

Mediastinoscopy is the traditional method for the evaluation of mediastinal lymph nodes in the staging of NSCLC. It has largely been replaced for most patients by a combination of positron-emission tomography scans and endobronchial ultrasound-guided biopsies. In addition, mediastinoscopy is used to aid in the diagnosis of anterior/superior mediastinal masses.[207] The most common mediastinal diagnostic procedure is a cervical mediastinoscopy, in which a small transverse incision (2-3 cm) is made in the midline of the lower neck in the suprasternal notch. The pretracheal fascial plane is dissected bluntly and the mediastinoscope inserted toward the carina. An alternative procedure is a parasternal (or anterior) mediastinoscopy with a small incision made through the interchondral space or the space of the excised second costal cartilage.

Morbidity related to mediastinoscopy ranges from 2% to 8%. The most severe complication of mediastinoscopy is major hemorrhage, which may require emergent thoracotomy. Other potential complications include airway obstruction, compression of the innominate artery, pneumothorax, paresis of the recurrent laryngeal, phrenic nerve injury, esophageal injury, chylothorax, and air embolism.[208]

Anesthetic Management

For patients undergoing cervical mediastinoscopy, it is important to review the chest radiograph and CT scan for the presence of a mass that might obstruct the airway during the preoperative evaluation. It is possible to perform mediastinoscopy (particularly anterior mediastinoscopy) with local anesthesia. This may be an option with an anterior mediastinal mass in a cooperative adult with a compromised airway. However, patient coughing or movement could result in surgical complications. The majority of these patients require general anesthesia with placement of an SLT. An arterial line is not necessarily used in these cases. However, it is mandatory to monitor the pulse in the right arm (pulse oximeter on the right hand, arterial line, or anesthesiologist's finger) because compression of the innominate artery by the mediastinoscope may occur and the surgeon usually is not aware that this is happening. The innominate artery supplies not only the right arm but also the right common carotid. Patients who do not have good cerebral collateral circulation (it is generally not possible to predict who these patients are) are at risk for cerebrovascular ischemia with innominate compression. A noninvasive blood pressure cuff is placed on the left arm to confirm the correct systolic pressure in case of suspected innominate compression.

Minor mediastinal hemorrhage may respond to conservative measures, such as placing the patient in the head-up position, keeping the systolic pressure in the 90s, and tamponading the wound with surgical sponges. However, massive hemorrhage requires an emergent sternotomy or thoracotomy to stop the bleeding (Box 53.13). A bronchial blocker can be passed through the lumen of the existing lung isolation device if lung isolation is required since it is often difficult to change to a DLT while the surgeon is tamponading the wound. An arterial line should be placed (if not placed previously) to measure arterial blood pressure. If hemorrhage originates from a tear in the superior vena cava, volume replacement and drug treatment may be lost into the surgical field unless they are administered through a peripheral intravenous line placed in the lower extremity.

Pneumothorax is an infrequent complication of mediastinoscopy. Pneumothorax that occurs intraoperatively (as evidenced by increased peak inspiratory pressure, tracheal shift, distant breath sounds, hypotension, and cyanosis) requires immediate treatment by chest tube decompression. All patients must have a chest radiograph taken in the postanesthesia care unit after mediastinoscopy to rule out pneumothorax.

When mediastinoscopy causes injury to the recurrent laryngeal nerve, it can be permanent in approximately 50% of the cases. If injury to the recurrent laryngeal nerve is suspected, the vocal cords should be visualized while the patient is spontaneously breathing. If the vocal cords do not move or are in a midline position, consideration has to be given to the problem of postoperative laryngeal obstruction.

BOX 53.13 **Anesthetic Management of Mediastinoscopy Hemorrhage**

1. Stop surgery and pack the wound. There is a serious risk that the patient will approach the point of hemodynamic collapse if the surgery-anesthesia team does not realize soon enough that there is a problem.
2. Begin the resuscitation and call for help, both anesthetic and surgical.
3. Obtain large-bore vascular access in the lower limbs.
4. Place an arterial line (if not placed at induction).
5. Prepare for massive hemorrhage with blood warmers and rapid infusers.
6. Obtain cross-matched blood in the operating room.
7. Place a double-lumen tube or bronchial blocker if the surgeon believes that thoracotomy is a possibility.
8. Once the patient is stabilized and all preparations are made, the surgeon can reexplore the cervical incision.
9. Convert to sternotomy or thoracotomy if indicated.

TABLE 53.10 Comparison of Surgical Approaches for Pulmonary Resections

Incision	Pro	Con
Posterolateral thoracotomy	Excellent exposure to entire operative hemithorax	Postoperative pain with or without respiratory dysfunction (short and long term)
Lateral muscle-sparing thoracotomy	Decreased postoperative pain	Increased incidence wound seromas
Anterolateral thoracotomy	Better access for laparotomy, resuscitation, or contralateral thoracotomy, especially in trauma	Limited access to posterior thorax
Axillary thoracotomy	Decreased pain. Adequate access for first rib resection, sympathectomy, apical blebs, or bullae.	Limited exposure
Sternotomy	Decreased pain Bilateral access	Decreased exposure of left lower lobe and posterior thoracic structures
Transsternal bilateral thoracotomy (“clamshell”)	Good exposure for bilateral lung transplantation	Postoperative pain and chest wall dysfunction
Video-assisted thoracoscopic surgery (VATS) or robotic surgery	Less postoperative pain and respiratory dysfunction	Technically difficult with central tumors and chest wall adhesions

During mediastinoscopy, the tip of the mediastinoscope is located intrathoracically and therefore it is directly exposed to pleural pressure. A venous air embolus can occur if venous bleeding occurs and patients are breathing spontaneously because of the development of negative intrathoracic pressure during inspiration. Autonomic reflexes may result from compression or stretching of the trachea, vagus nerve, or great vessels. With an uncomplicated mediastinoscopy, the patient can be extubated in the operating room and discharged home the same day.

ENDOBRONCHIAL ULTRASOUND-GUIDED BIOPSY

Various alternative techniques are available for obtaining pathology specimens from the mediastinal lymph nodes. These include CT-guided percutaneous needle aspiration, conventional bronchoscopy with transbronchial needle aspiration, and endobronchial ultrasound-guided biopsy. Endobronchial ultrasonography (EBUS) employing a radial probe through a working channel of the flexible fiberoptic bronchoscope can be used to identify mediastinal and hilar lymph nodes.[209] Under direct EBUS guidance with fine-needle aspiration for mediastinal staging, an ultrasound puncture bronchoscope can be used to assist with the safe and accurate diagnostic interventional bronchoscopy of the mediastinal and hilar lymph nodes. Management of these patients is often done at a satellite location, either in the bronchoscopy facility or CT suite. In general, these patients are managed with topical anesthesia (aerosolized lidocaine) and conscious sedation (e.g., fentanyl and/or midazolam). When general anesthesia is used, it is preferable to place an LMA or a large diameter (≥8.5 mm ID) ETT because of the large diameter of the EBUS bronchoscope,

Pulmonary Surgery

Any given pulmonary resection can be accomplished by a variety of different surgical approaches. The approach used in an individual case will depend on the interaction of several factors that include the site and pathology of the lesion(s) and the training and experience of the surgical team. Common thoracic surgical approaches and their generally accepted advantages and disadvantages are listed in Table 53.10.

MINIMALLY INVASIVE THORACOSCOPIC SURGERY

VATS is the procedure of choice for the diagnosis and management of diseases of the pleura, nondiagnosed peripheral pulmonary nodules, and interstitial lung disease (Fig. 53.45). Since the start of the modern era of thoracoscopic surgery in the early 1990s, VATS has been proposed as a less invasive approach than open thoracotomy. Today it is a well-accepted and established operation and has become the first-choice technique for lung biopsies, pleurectomies, sympathectomies, and other various pulmonary procedures.[210]

In addition, VATS may be used in a variety of other surgical procedures. Some centers routinely perform the majority of lobectomies under VATS. The outcomes for VATS lobectomies in patients with limited respiratory reserves seems superior to that for open thoracotomy.[211] Other surgeries, such as spinal fusion and scoliosis, have been performed with VATS. The advantages of VATS, when compared to open thoracotomy, include: (1) reduced hospital length of stay, (2) less blood loss if no mishaps occur, (3) less pain, (4) improvement in pulmonary function when compared with open thoracotomy,[212] (5) early patient mobilization with early recovery and rapid return to work and daily activities, and (6) less inflammatory reaction, as measured by cytokine response in patients undergoing VATS lobectomy compared to open thoracotomy.[213]

VATS lobectomy has been demonstrated to be a safe and effective procedure to treat early-stage NSCLC.[214] Thoracoscopic lobectomy is performed with a limited number of ports and an access incision of approximately 5 cm in length.[215] The advantage of the VATS technique is that

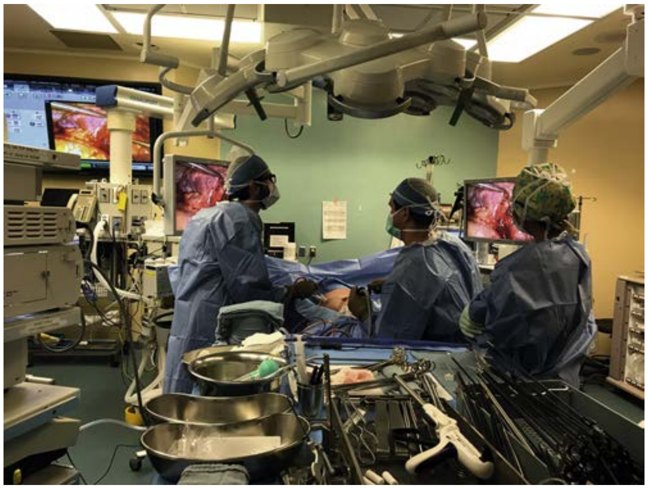

Fig. 53.45 Intraoperative photograph during video-assisted thoracoscopic surgery seen from the foot of the operating table. Multiple high-definition video screens facilitate communication between the anesthesiologist and the surgeon on the progress of the procedure.

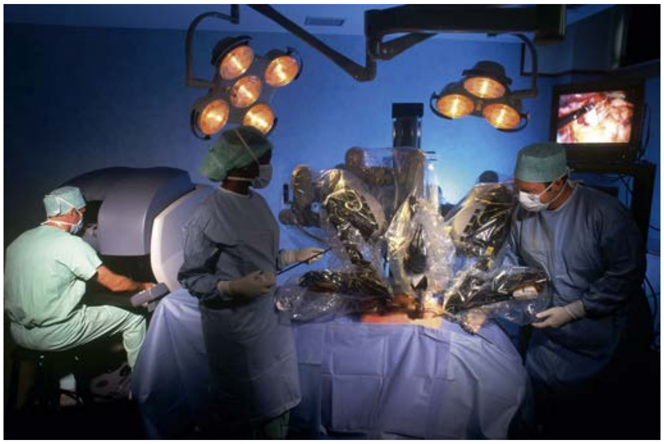

Fig. 53.46 Robotic surgery. The operating surgeon is on the far left in the photograph seated at the robot consol. Note the limited access to the patient for the anesthesiologist after the robot has been docked.

the ribs are not spread. VATS procedures are commonly performed in the lateral decubitus position; however bilateral VATS procedures, such as bilateral wedge resections or lung volume reduction, can be performed in the supine position. There is a trend to use only one port for VATS surgery.[216] Uniportal VATS may be associated with decreased postoperative pain and a shorter length of hospital stay.

Robotic thoracic surgery has been suggested as the logical advancement of VATS because of the perceived superior three-dimensional vision and increased range of motion in the chest for the surgeon with robotic techniques (Fig. 53.46).[217] Important points in anesthetic management are outlined in Box 53.14.

BOX 53.14 Anesthetic Considerations for Robotic Thoracic Surgery

1. A protocol for rapid emergency undocking (<60 s) of the robot must be developed and practiced in advance.
2. Limited access to the patient. The position of lung isolation device needs to be confirmed prior to docking the robot.
3. Extensions to monitoring lines and anesthesia circuit may be required.
4. There is an increased need for intrathoracic CO_2 insufflation with possible venous return and hemodynamic compromise.
5. Take precautions so that the operating room table cannot be moved while the robot is docked.
6. There is an increased risk of positional neuropathies because of potentially prolonged procedures; therefore fluid restriction is advisable.

ANESTHETIC TECHNIQUE

Thoracoscopic surgery can be performed under local, regional, or general anesthesia with OLV or TLV.[218] For minor diagnostic procedures, VATS can be done in the awake patient. Intercostal nerve blocks performed at the level of the incision and two interspaces above and below provide adequate analgesia. Partial collapse of the lung on the side of surgery occurs when air enters the pleural cavity. When using local anesthesia with the patient awake, it is hazardous to insufflate gases under pressure into the hemithorax in an attempt to increase visualization of the pleural space. Although many patients suffer from advanced pulmonary disease, changes in PaO_2, $PaCO_2$, and cardiac rhythm are usually minimal during the procedure when it is performed under local anesthesia and the patient is breathing spontaneously.[219] However, it is recommended that a high FiO_2 is delivered via a facemask to overcome the shunt because of the loss in lung volume caused by the unavoidable pneumothorax.

For most invasive procedures VATS is performed under general anesthesia with a DLT or a bronchial blocker to achieve OLV. If the procedure is short in duration and the lung needs to be deflated for only a brief period, blood gases are not routinely monitored during the procedure. However, for patients undergoing prolonged VATS procedures such as lobectomy or for patients with marginal pulmonary status, an arterial line and measurement of arterial blood gases is required. Paravertebral blocks have been used with a single dose of local anesthetics and have been shown to reduce pain for 6 hours after thoracoscopic surgery.[220]

Anesthetic complications are rare during this procedure, although it is possible that any structure that the surgeon has to manipulate may be damaged. The anesthesiologist needs to be aware of the potential for conversion to open thoracotomy if massive bleeding ensues, or the surgeon is unable to localize the lung nodule to be biopsied. The majority of thoracoscopic surgery requires placement of a chest tube postoperatively. It is important to have a functional chest tube with underwater seal drainage so that extubation can be performed safely.

Lobectomy

Lobectomy is the standard operation for the management of lung cancer because local recurrence of the tumor is reduced compared to lesser resections. Lobectomy is commonly performed via open thoracotomy or VATS. Occasionally, if the clinical staging of the lung cancer is advanced, an elective lobectomy is converted to a bi-lobectomy (right lung) or pneumonectomy during the operation. Although a posterolateral thoracotomy is the classic incision for lobectomies, anterolateral and muscle-sparing lateral incisions have also been used.

Postoperative analgesia is commonly performed with TEA or paravertebral analgesia for open procedures (see “Postoperative Analgesia” later in the chapter). An arterial line for management of arterial blood gases and measurement of systemic blood pressure is used in all patients requiring an open thoracotomy or major VATS surgery. It is useful to have two lines of intravenous access, at least one of which is large-bore, to facilitate rapid transfusion if necessary. Patients undergoing a lobectomy must be kept normothermic, normotensive, and with an acceptable PaO_2 and oxygen saturation, particularly during OLV. Patients should have a thermal blanket on the lower extremities to prevent hypothermia and its deleterious effects during HPV. After the lobe and blood vessels have been dissected, a test maneuver is performed with the surgeon clamping the surgical bronchus to confirm that the specific lobe is extirpated. This maneuver is accomplished by unclamping the limb of the DLT connector of the respective side, or in the case of a bronchial blocker, by deflating the blocker balloon, and reexpanding the lung with manual ventilation. During VATS lobectomy, as a result of the interference to the surgical field caused by reinflating the residual lobe, the anesthesiologist may be asked to fiberoptically inspect the bronchial tree to confirm patency of the bronchus of the noninvolved lobe(s). Once the lobectomy has been performed, the bronchial stump is usually tested with 20 cm H_2O positive pressure in the anesthetic circuit to detect the presence of air leaks. A patient undergoing an uncomplicated lobectomy can be usually extubated in the operating room provided preoperative respiratory function is adequate (see “Preoperative Evaluation of the Thoracic Surgery Patient” earlier in the chapter) and the patient is AWaC.

Pancoast tumors are carcinomas of the superior sulcus of the lung and can invade and compress local structures including the lower brachial plexus, subclavian blood vessels, stellate ganglion (causing Horner syndrome), and vertebrae. Lobectomy may require a two-stage procedure with an initial operation for posterior instrumentation/stabilization of the spine. During lobectomy, extensive chest wall resection may be required and massive transfusion is a possibility. Peripheral lines and monitoring should be in the contralateral arm due to frequent compression of the ipsilateral vessels during surgery.

SLEEVE LOBECTOMY

Bronchial sleeve resections are performed for neoplasms or benign strictures. Bronchogenic carcinoma is the most frequent indication for a sleeve lobectomy, followed by carcinoid tumors, endobronchial metastases, primary airway tumors, and bronchial adenomas. Sleeve lobectomy involving parenchyma-sparing techniques in patients with limited pulmonary reserve is an alternative procedure for patients that cannot tolerate a pneumonectomy. The sleeve technique involves mainstem bronchial resection without parenchymal involvement and possibly resection of pulmonary arteries to avoid pneumonectomy (Fig. 53.47).

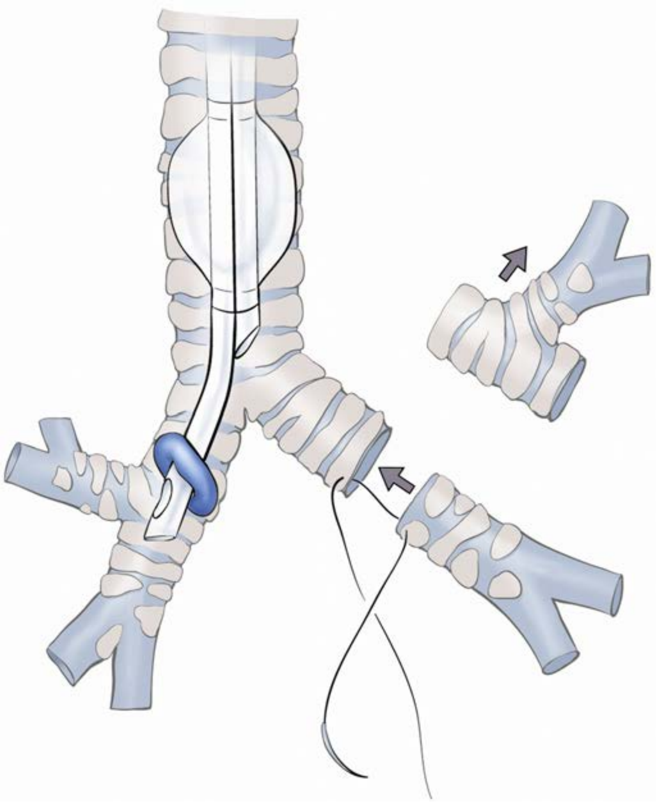

Fig. 53.47 Diagram of the surgical procedure for a left upper sleeve lobectomy. Airway management is with a right-sided double-lumen tube. Note that it will not be possible to position an endobronchial tube or bronchial blocker in the ipsilateral mainstem bronchus during this procedure.

Patients undergoing sleeve lobectomy require lung isolation with a contralateral DLT or endobronchial tube (i.e., use a right-sided DLT for a left sleeve lobectomy). High-frequency jet ventilation (HFJV) can be used for resections close to the tracheal carina. For a sleeve lobectomy involving resection of vessels, heparinization is necessary. In these cases, thoracic epidural catheters should not be manipulated for 24 hours following heparin administration. During pulmonary arterioplasty, uncontrollable bleeding may occur. For this reason, large-bore intravenous catheters should be used. Patients undergoing sleeve lobectomy are usually extubated in the operating room before transfer to the postanesthesia recovery room. Immediate and long-term survival is better after sleeve lobectomy compared with right pneumonectomy for comparable stages of right upper lobe cancer.[221]

Pneumonectomy

Complete removal of the lung is required when a lobectomy or its modifications is not adequate to remove the local disease and/or ipsilateral lymph node metastases. Atelectasis and pneumonia occur following pneumonectomy as they do following lobectomy but may in fact be less of a problem because of the absence of residual parenchymal dysfunction on the operative side. However, the mortality rate following pneumonectomy exceeds that for lobectomy because of postoperative cardiac complications and acute lung injury.

The overall operative mortality for the first 30 days after pneumonectomy ranges from 5% to 13% and correlates inversely with the surgical case volume.[222] The risk of complications increases fivefold in patients age 65 and older.[223]

Thoracotomy for pneumonectomy is usually performed through a standard posterolateral incision. After all vessels are stapled, stapling of the bronchus occurs and the entire lung is taken from the chest. A test for air leaks is generally performed at this point and reconstruction of the bronchial stump is completed. The bronchial stump should be as short as possible to prevent a pocket for the collection of secretions.

There is no consensus among thoracic surgeons on the best method of management of the postpneumonectomy space. If suction is applied to an empty hemithorax or a chest drain is connected to a standard underwater-seal system it may cause a mediastinal shift with hemodynamic collapse. Some thoracic surgeons do not place a chest drain after a pneumonectomy; some prefer to use a temporary drainage catheter to add or remove air. The removal of air, ranging from 0.75 up to 1.5 L, is necessary to empty the chest and to keep the mediastinum ("balanced") and the trachea in the midline. Some surgeons place a specifically designed postpneumonectomy chest drainage system with both high- and low-pressure underwater relief valves to balance the mediastinum.[224] A chest radiograph is mandatory after the patient arrives in the postanesthesia care unit or in the surgical intensive care unit to assess the mediastinal shift.

The patient scheduled to undergo a pneumonectomy is considered at high risk for perioperative morbidity and mortality. The placement of large-bore intravenous lines is necessary in case blood products need to be administered. An invasive arterial line is placed for measurement of beat-to-beat blood pressure and to monitor arterial blood gases. A CVP catheter is recommended to help guide intravascular fluid management and to administer vasopressors if needed, specifically in the postoperative period.

A major lung resection, such as pneumonectomy, decreases ventilatory function and has significant effects on the right ventricular function.[225] Immediately after pneumonectomy, the right ventricle may dilate and the right ventricular function decrease. Increased right ventricular afterload is due to an increase in pulmonary artery pressure and PVR. This is considered to be one of the main causes of right ventricular dysfunction after a major lung resection.

Management of lung isolation in a pneumonectomy patient can be achieved with a DLT, bronchial blocker, or SLT. When using a DLT for a pneumonectomy patient, it is optimal to use a device that does not interfere with the ipsilateral airway (i.e., for a right pneumonectomy a left-sided DLT). If a left-sided DLT or bronchial blocker is used for a left pneumonectomy, it must be withdrawn prior to stapling the bronchus, in order to avoid accidental inclusion into the suture line.

Specific areas of concern in the management of the patient undergoing pneumonectomy include: (1) fluid management, (2) intraoperative tidal volume, and (3) acute lung injury postsurgery. Fluid administration after major lung resection continues to be an issue. In a retrospective report by Zeldin and associates,[226] the risk factors that were identified for the development of acute lung injury ("postpneumonectomy pulmonary edema") were a right-sided pneumonectomy, increased perioperative intravenous fluid administration, and increased urine output in the postoperative period. A more recent study by Licker and colleagues has shown that the excessive administration of intravenous fluids in thoracic surgical patients (more than 3 L in the first 24 hours) is an independent risk related to an acute lung injury.[227] There is reasonable clinical evidence that excessive fluid administration is associated with the development of an acute lung injury, which has a high mortality rate following pneumonectomy. Consequently, pneumonectomy patients should have restricted intraoperative fluid administration while preserving renal function. Some cases may require the use of inotropes/vasopressors to maintain hemodynamic stability while restricting fluids (see Box 53.11).

Respiratory failure is a leading cause of postoperative morbidity and mortality in patients undergoing pneumonectomy. A retrospective report[228] involving 170 pneumonectomy patients showed that patients that received median tidal volumes greater than 8 mL/kg had a greater risk of respiratory failure in the postoperative period after pneumonectomy. In contrast, patients that received tidal volumes less than 6 mL/kg were at lower risk of respiratory failure. Schilling and associates[229] have shown that a tidal volume of 5 mL/kg during OLV significantly reduces the inflammatory response to alveolar cytokines. Considering these factors, it is prudent to use lower tidal volumes (i.e. 6 mL/kg, ideal body weight) in the pneumonectomy patient, and limit peak and plateau inspiratory pressures (i.e., <35 and 25 cm H_2O, respectively) during OLV.

The incidence of acute lung injury (postpneumonectomy pulmonary edema) after pneumonectomy is only 4%. However, the mortality rate is 30% to 50%. The etiology seems multifactorial. One study[229] has identified four independent risk factors for acute lung injury after pulmonary resection: (1) pneumonectomy, (2) excessive administration of fluids in the intraoperative period, (3) high intraoperative ventilatory pressure index (combined airway pressure and time), and (4) preoperative alcohol abuse. The incidence of an acute lung injury is greater for a right-sided versus left-sided pneumonectomy. This may be related to the higher postoperative pulmonary artery pressures after a right versus left pneumonectomy (Fig. 53.48).[230] At the present time only symptomatic management is appropriate for this lung injury. This includes fluid restrictions, diuretic administration, low ventilatory pressures and tidal volumes (if mechanical ventilation is used), and measures to decrease the pulmonary artery pressure. ECMO may be useful in managing this complication.[231]

EXTRAPLEURAL PNEUMONECTOMY

Extrapleural pneumonectomy is a therapeutic option for selected patients with MPM.[232] Significant improvement in survival has been achieved in patients who have an advanced MPM with extrapleural pneumonectomy and high-dose radiotherapy in the postoperative period. Extrapleural pneumonectomy involves an extensive resection that may include lymph nodes, pericardium, diaphragm, parietal pleura, and the chest wall. The anesthetic management of the extrapleural pneumonectomy patient is

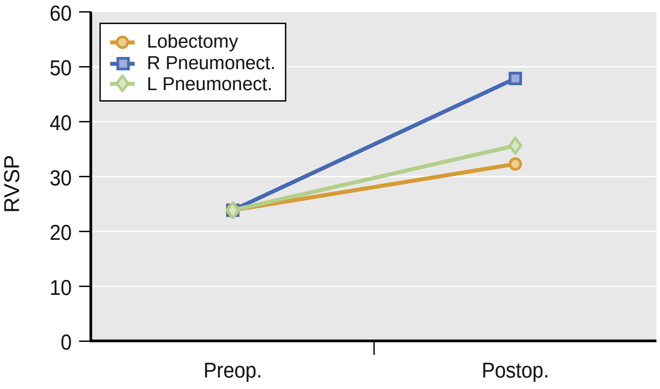

Fig. 53.48 Comparison of right ventricular systolic pressure *(RVSP)* measured by echocardiography in patients before (Preop.) and at 6 months after (Postop.) pulmonary resections. *L Pneumonect*, Left pneumonectomy; *R Pneumonect*, right pneumonectomy. Note the elevated RVSP, and therefore pulmonary artery pressure, after a right pneumonectomy. (Based on data from Foroulis C, et al. *Eur J Cardiothorac Surg.* 2004;26:508.)

characterized by significant loss of blood because of chest wall vessel involvement. In these patients, it is recommended that a CVP catheter be used to guide intravascular fluid administration and insure large-bore intravenous access. During tumor dissection, venous return to the heart may be compromised due to multiple factors including blood loss, compression effect by the tumor in superior vena cava, or surgical causes. If excessive bleeding ensues, it must be replaced to maintain an acceptable hematocrit and to keep the coagulation profile within normal limits. Because of extensive tumor resection and the potential for a pericardial resection in right-sided surgery, cardiac herniation or hemodynamic instability can appear postoperatively after the patient is turned from lateral decubitus to supine position. It is common to ventilate these patients for a short period postoperatively because of the extended duration of the surgery and the large fluid shifts. If a DLT is used intraoperatively, the DLT is usually replaced at the end of the case with an SLT.

SLEEVE PNEUMONECTOMY

Tumors involving the most proximal portions of the mainstem bronchus and the carina may require a sleeve pneumonectomy. These are most commonly performed for right-sided tumors and can usually be performed without ECMO via a right thoracotomy. A long SLT can be advanced across into the left mainstem bronchus during the period of tracheobronchial anastomosis. High-frequency positive-pressure ventilation (HFPPV) has also been used for this procedure and the combined use of HFPPV and a DLT has been described.[233] Since the carina is surgically more accessible from the right side, left sleeve pneumonectomies are commonly performed as a two-stage operation: first there is a left thoracotomy and pneumonectomy followed by a right thoracotomy for the carinal excision. The complication rate and mortality are higher, and the 5-year survival (20%) significantly lower than for other pulmonary resections. Postpneumonectomy pulmonary edema is particularly a problem following right sleeve pneumonectomy.

Limited Pulmonary Resections: Segmentectomy and Wedge Resection

A limited pulmonary resection is one in which less than a complete lobe is removed. The two procedures fitting this definition are segmentectomy and wedge resection. Segmentectomy is an anatomic pulmonary resection of the pulmonary artery, vein, bronchus, and parenchyma of a particular segment of the lung. Segmentectomy is usually performed as surgical therapy for patients with primary lung cancer and limited cardiorespiratory reserves. In contrast, a wedge resection is a nonanatomic removal of a portion of the lung parenchyma with a 1.5- to 2.0-cm margin and can be accomplished by open thoracotomy or VATS. Wedge resections are most commonly performed for diagnosis of lung lesions with unknown histology or as palliation in patients with metastatic lesions in the lungs from distant primary tumors. Lung cancers that are considered for limited resection are usually less than 3 cm in size and are located in the periphery of the lung with regional lymph nodes free of metastatic cancer. Small peripheral lung lesions may be localized preoperatively for VATS resection by CT placement of a marker such as a coil.[234] The relevance of this for anesthesia is that the CT procedure may cause a pneumothorax and possibly a bronchopleural fistula. To avoid a possible tension pneumothorax at induction, positive-pressure TLV should be avoided (or minimized) and lung isolation with OLV commenced as soon as possible.

A group of patients considered for limited pulmonary resection are those who develop a new primary lesion after a previous lobectomy or pneumonectomy. The patient with compromised lung function presents a greater risk in the intraoperative period (hypoxemia during OLV or prolonged intubation after surgery). Cerfolio and associates[235] reported that lung cancer patients with compromised pulmonary function can safely undergo limited pulmonary resection if selected appropriately. Segmentectomies and wedge resections can be performed with any of the standard thoracotomy or VATS incisions. Segments that are most commonly resected are in the upper lobes or the superior segments of the lower lobes.

Anesthetic technique and monitoring are essentially the same as for larger pulmonary resections. In order to facilitate surgical exposure and achieve OLV, it is necessary to use either a DLT or a bronchial blocker. If the patient had a previous contralateral lobectomy or a pneumonectomy, selective lobar collapse with the use of a bronchial blocker will facilitate surgical exposure while maintaining oxygenation. In selected cases, the combined use of a DLT and a bronchial blocker will allow selective lobar collapse/ventilation in the ipsilateral lung.[236] It is very important to use low tidal volumes (i.e., 3-4 mL/kg) during selective lobar ventilation, particularly in patients with previous pneumonectomy to prevent overinflation in the remaining lobes.

Segmentectomy plays a significant role in the management of patients with a second primary lung cancer. Many of these patients have previously undergone thoracic surgery, including previous lobectomy or pneumonectomy; therefore the potential for increased intraoperative bleeding is always a risk. In addition, because many of these patients have compromised lung function, early extubation may not be feasible. A common complication after surgery is an air leak. Chest tubes are placed to maximize postoperative expansion and minimize space complications. Suction and underwater-seal chest drainage is used in the postoperative period.

Anesthetic Management for Specific Surgical Procedures

ESOPHAGEAL SURGERY

Esophageal surgery is performed for both malignant and benign disease and may be curative or palliative. General considerations that apply to many esophageal surgery patients include an increased risk of aspiration caused by esophageal dysfunction and the possibility of preoperative malnutrition.

Esophagectomy

Esophagectomy is a palliative and potentially curative treatment for esophageal cancer and may occasionally be required for some benign obstructive lesions which do not respond to conservative therapy. It is a major surgical procedure and is associated with high morbidity and mortality rates (10%–15%). There is an inverse correlation between perioperative mortality and surgical volume and the cure rate of esophageal cancer with esophagectomy is between 10% and 50%. There are multiple surgical procedures for esophageal cancer (Table 53.11) that combine some or all of three fundamental approaches: (1) transthoracic approach, (2) transhiatal approach, and (3) minimally invasive surgery (laparoscopic/thoracoscopic or robotic esophagectomy).[237] The incidence of respiratory complications has been reported to be between 18% and 26% for both the transthoracic and transhiatal esophagectomy approaches.[238] One study showed that the development of acute respiratory distress syndrome occurred in 14.5% of patients and acute lung injury in 24%.[239] Complications associated with the gastroesophageal anastomosis are anastomotic leakage/dehiscence (5%–26%) and stenosis (12%–40%). Outcomes are improved with a multimodal anesthetic management protocol using fluid restriction, early extubation, thoracic epidural analgesia, and vasopressor/inotrope infusions to support blood pressure.[240] Hypotension decreases the blood flow to the esophagogastric anastomosis. The use of vasopressors or inotropes, in normovolemic patients, restores the systemic pressure and the anastomotic blood flow.[241] Fluid management for esophageal surgery is essentially the same as for pulmonary resection surgery.

Transthoracic Approach. Transthoracic esophagectomy is commonly a two-phase procedure. The first phase involves a laparotomy performed with the patient in the supine position and the creation of a neoesophagus tube using the stomach. The second phase involves a right-sided thoracotomy in the left lateral position and esophageal reconstruction through the thoracic route. Some surgeons may perform this procedure through an extended left thoracoabdominal incision.

The anesthetic management for these patients includes the use of standard monitors, an invasive arterial line, and a CVP catheter to the large fluid shifts. Access to the right internal jugular is not a problem; however there is always a possibility of a surgical esophageal anastomosis in the left neck contraindicating access to the left internal jugular. A thoracic epidural catheter is usually placed to provide postoperative analgesia. Because of the wide number of dermatomes that must be covered for both incisions by the epidural infusion, it is best to use hydrophilic opioids (such as hydromorphone) in combination with local anesthetics in preference to lipophilic opioids. Most patients with an esophageal carcinoma have gastric reflux; for this reason, precautions (including a rapid-sequence induction with cricoid pressure) should be taken to protect the airway against aspiration.

During the second phase (right thoracotomy), a left-sided DLT or a right-sided bronchial blocker is required to facilitate lung collapse. Because esophagectomy requires a prolonged period of OLV, this procedure is marked by

TABLE 53.11 Surgical Approaches for Esophagectomy and Esophagogastrectomy

Surgery	Incisions	Anesthetic Considerations
Laparotomy and right thoracotomy ("Ivor Lewis")	Two incisions: upper abdominal midline, right thoracotomy at approx. 5th or 6th intercostal space	One-lung ventilation necessary. Repositioning of patient intraoperatively from supine to right lateral
Transhiatal ("Orringer") (lower-third lesions; may be used for mid-third in some centers)	Two incisions: upper abdominal midline and left neck	Hemodynamic instability from cardiac compression during blunt intrathoracic dissection. Possibility of occult perforation of tracheobronchial tree during blunt dissection (may need to advance endotracheal tube into bronchus) No vascular access in left neck
Left thoracoabdominal (lower esophageal lesions only)	One incision: left lateral thoracotomy extended to left upper lateral abdominal	One-lung ventilation desirable
Combined chest, abdominal, and neck ("three hole"; upper and mid-esophageal lesions)	Three incisions: right thoracotomy, laparotomy, left neck	One-lung ventilation necessary Repositioning lateral to supine intraoperatively No vascular access in left neck
Minimally invasive, laparoscopy plus VATS or robotic surgery	One to three small incisions plus video port access. Possible left neck incision at end.	One-lung ventilation necessary Potentially prolonged surgery

VATS, Video-assisted thoracoscopic surgery.

an important inflammatory response. Michelet and colleagues[242] have shown that the use of protective ventilatory strategies during OLV decrease the proinflammatory systemic response. This decreased response can be achieved by delivering 5 mL/kg of tidal volume and a PEEP of 5 cm H_2O to the dependent lung, instead of the 9 mL/kg of tidal volume that is conventionally used during esophagectomy.

Manipulation of the esophagus during thoracotomy may compromise venous return, which can cause hypotensive episodes. Early extubation in the operating room is encouraged if the patient meets standard criteria for extubation. If extubation is not possible, the DLT should be exchanged for an SLT and mechanical ventilation used in the postoperative period.

Transhiatal Approach. Airway management is done with an SLT. Apart from this, anesthetic management is essentially the same as for a transthoracic approach. Of special concern is that the blunt/blind manual dissection of the thoracic esophagus by the surgeon through the hiatus during this approach is often associated with cardiac compression and sudden severe hypotension. Also, this blind dissection can cause vascular or distal airway injuries if the tumor is adherent.[243] It is a good practice to not cut the ETT for this procedure in case of surgical perforation of the trachea or bronchus necessitating advancement of the ETT into a mainstem bronchus for emergent OLV.

Minimally Invasive Approach. Minimally invasive esophagectomy involves the use of laparoscopic, thoracoscopic, and/or robotic surgical approaches. For a laparoscopic approach, distension of the peritoneum may produce hemodynamic changes because of the intragastric pressure generated by carbon dioxide insufflation. In these cases, it is important to adjust ventilatory parameters to achieve an optimal $PaCO_2$. For the thoracoscopic approach, a left-sided DLT or a bronchial blocker is required. During robotic surgery, the use of a lung isolation device is required to achieve OLV. Special considerations for robotic surgery include protecting the patient against any injury related to the robot and not moving the operating room table while the robot is being used. The thoracoscopic-assisted esophagectomy has several advantages including less blood loss, less pain, and a shorter length of hospitalization. This method may require a prolonged duration of surgery. Some centers favor performing the VATS portion of a minimally invasive esophagectomy in the prone position to improve surgical access.[244] Lung isolation for these cases is usually with a bronchial blocker via an SLT.

Patients undergoing esophagectomy usually require a nasogastric tube, which must be well-secured at the end of the operation. Respiratory complications, including the development of an acute lung injury, may be present after an esophagectomy. Intrathoracic anastomotic leakage is a feared major complication after esophageal surgery, and carries a high mortality rate of 4% to 30%.[245] To treat this potential complication, nasogastric decompression and nutritional support should be used. Severe leakage usually occurs in the early postoperative period as a consequence of gastric necrosis, and it may present with respiratory symptoms and signs of shock. Even though there is a very high mortality rate, prompt surgical intervention is recommended. Patients older than 80 years have an increased risk of mortality after esophagectomy, independent of comorbidity.[246]

Esophageal Surgery for Benign Disease

Hiatal Hernia. Although most patients with gastroesophageal reflux have a hiatal hernia, most patients with a hiatal hernia do not have significant reflux.[247] Patients with heartburn have a lowered barrier pressure and may be at increased risk for regurgitation of gastric contents. Two types of hiatal hernia have been described. Type I hernias, also called sliding hernias, make up approximately 90% of esophageal hiatal hernias. In this type, the esophagogastric junction and fundus of the stomach have herniated axially through the esophageal hiatus into the thorax (Fig. 53.49). The term sliding refers to the presence of a sac of parietal peritoneum. The lower esophageal sphincter is cephalad to the diaphragm and may not respond appropriately to increased abdominal pressure. Thus a reduced barrier-pressure during coughing or breathing leads to regurgitation. The type II or paraesophageal hiatus hernia is characterized by portions of the stomach herniating into the thorax next to the esophagus. In the presence of a type II hernia, the esophagogastric junction is still located in the abdomen. The most common complications from type II hernias are blood loss, anemia, and gastric volvulus.

The goal of surgical repair of a sliding hernia is to obtain competence of the gastroesophageal junction. Since restoration of the normal anatomy is not always successful in preventing subsequent reflux, several antireflux operations have been developed, such as the Nissen fundoplication. Repair of a hiatal hernia can be performed via a thoracotomy or laparotomy, or minimally invasively.

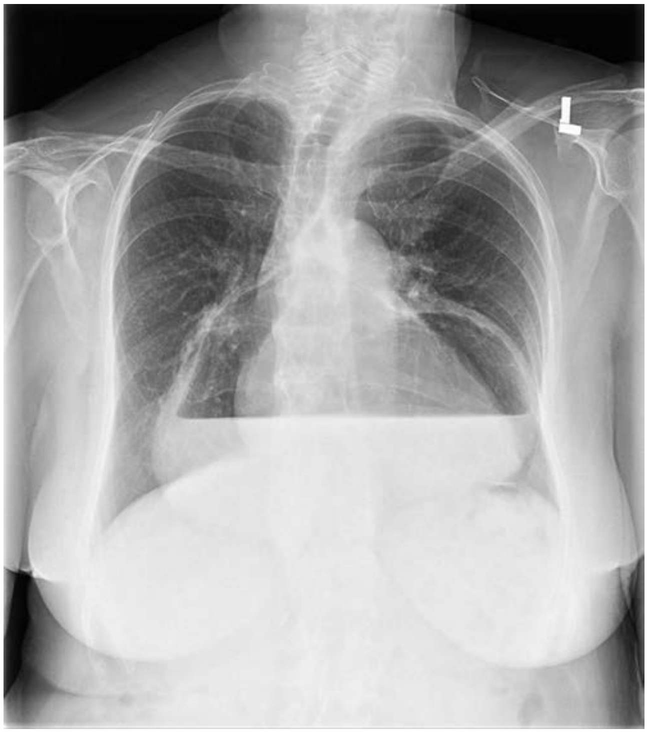

Fig. 53.49 Chest radiograph of a patient with a hiatal hernia and a dilated intrathoracic stomach, scheduled for hiatal hernia repair via a left thoracotomy. An air-fluid level can be seen in the stomach behind the heart. These patients are at high risk for aspiration on induction of anesthesia.

Benign Esophageal Stricture. Chronic reflux of acidic gastric contents can lead to ulceration, inflammation, and eventually stricture of the esophagus. The pathologic changes are reversible if the acidic gastric contents cease their contact with the esophageal mucosa. Surgery may be necessary if medical treatment and dilatations are inadequate. There are two types of surgical repair, both of which are usually approached via a left thoracoabdominal incision. Gastroplasty after esophageal dilatation interposes the fundus of the stomach between esophageal mucosa and the acidic milieu of the stomach. The remaining fundus may be sewn to the lower esophagus to create a valvelike effect. The second type of repair is resection of the stricture and the creation of a thoracic end-to-side esophagogastrostomy. Vagotomy and antrectomy are performed to eliminate stomach acidity, and a Roux-en-Y gastric drainage procedure is performed to prevent alkaline intestinal reflux.

Esophageal Perforation and Rupture. There are multiple causes of esophageal perforation, including foreign bodies, endoscopy, bougienage, traumatic tracheal intubation, gastric tubes, and oropharyngeal suctioning. Iatrogenic causes are the most common, with upper gastrointestinal endoscopy being the most frequent cause. A rupture is a burst injury often due to uncoordinated vomiting, straining associated with weight-lifting, childbirth, defecation, and crush injuries to the chest and abdomen. The rupture is usually located within 2 cm of the gastroesophageal junction on the left side. Rupture is the result of a sudden increase in abdominal pressure with a relaxed lower esophageal sphincter and an obstructed esophageal inlet. In contrast to a perforation, in the presence of a rupture, the stomach contents enter the mediastinum under high pressure and the patient becomes symptomatic much more abruptly.

In addition to chest and/or back pain, patients with intrathoracic esophageal perforation or rupture may develop hypotension, diaphoresis, tachypnea, cyanosis, emphysema, and hydrothorax or hydropneumothorax.[248] Radiologic studies may reveal subcutaneous emphysema, pneumomediastinum, widening of the mediastinum, pleural effusion, and pneumoperitoneum. In some cases, minor perforations can be managed conservatively. Major injuries will rapidly develop mediastinitis and sepsis if not treated surgically, so repair and drainage is an emergency procedure usually performed via a left or right thoracotomy.

Achalasia. Achalasia is a disorder in which there is a lack of peristalsis of the esophagus and a failure of the lower esophageal sphincter to relax in response to swallowing. Clinically, the patients have esophageal distention that may lead to chronic regurgitation and aspiration. The goal of treatment is to alleviate the distal obstruction. This can be done by either esophageal dilatation or by surgery. Dilatation, which carries with it the risk of perforation, can be achieved by mechanical, hydrostatic, or pneumatic means. The surgical repair consists of a Heller myotomy, which is an incision through the circular muscle of the esophagogastric junction. The myotomy is often combined with a hiatal hernia repair to prevent subsequent reflux. This can be performed via thoracotomy, laparotomy, or laparoscopy.[249] This procedure can also be performed endoscopically. Peroral endoscopic myotomy (POEM) requires general anesthesia with endotracheal intubation.[250] Insufflation of CO_2 via the endoscope frequently leads to pneumoperitoneum, which requires abdominal decompression during the procedure.

Esophagorespiratory Tract Fistula. Esophagorespiratory tract fistula in an adult is most often due to malignancy. Occasionally, the fistula is benign, and may be due to injury by a tracheal tube, trauma, or inflammation. Of the malignant fistulae, approximately 85% are secondary to esophageal cancer. In contrast to the pediatric patient with esophagorespiratory tract fistulae, which usually connect the distal esophagus to the posterior tracheal wall, these fistulae may connect to any part of the respiratory tract.[251] In most cases, the fistula can be seen on esophagoscopy or bronchoscopy. In malignant cases, the goal of surgery is usually palliation. The technique of lung isolation will depend on the location of the fistula. One option in adults with a distal tracheal fistula is the use of bilateral small (5–6 mm ID) endobronchial tubes.[252]

Zenker Diverticulum. Zenker diverticulum is actually a diverticulum of the lower pharynx. It arises from a weakness at the junction of the thyropharyngeus and cricopharyngeus muscles just proximal to the esophagus. It is commonly considered as an esophageal lesion because of its proximity to the upper esophagus and because the underlying cause may be a failure of relaxation of the upper esophageal sphincter during swallowing. Early symptoms may be nonspecific with dysphagia and complaints of food sticking in the throat. As the diverticulum enlarges patients describe noisy swallowing, regurgitation of undigested food, and supine coughing spells. Recurrent aspiration and pneumonia may develop.

The major concern for anesthesia is the possibility of aspiration on induction of general anesthesia for excision of the diverticulum.[253] Even prolonged fasting does not ensure that the diverticulum will be empty. The best method to empty the diverticulum is to have the patient express and regurgitate the contents immediately prior to induction. Many of these patients will be used to doing this on a regular basis at home. Since the diverticulum orifice is almost always above the level of the cricoid cartilage, cricoid pressure during a rapid-sequence induction does not prevent aspiration and may contribute to aspiration by causing the sac to empty into the pharynx. Surgical excision is usually done through a lower left neck incision.

The safest method of managing the airway for these patients may be awake fiberoptic intubation. However, intubation has been managed without incident using a modified rapid-sequence induction without cricoid pressure and with the patient supine and in a head-up position of 20 to 30 degrees. Other considerations in these patients include the possibility of perforation of the diverticulum when passing an orogastric or nasogastric tube or an esophageal bougie.

Anesthesia for Tracheal Resection

Tracheal resection and reconstruction is indicated in patients who have a tracheal obstruction as a result of a

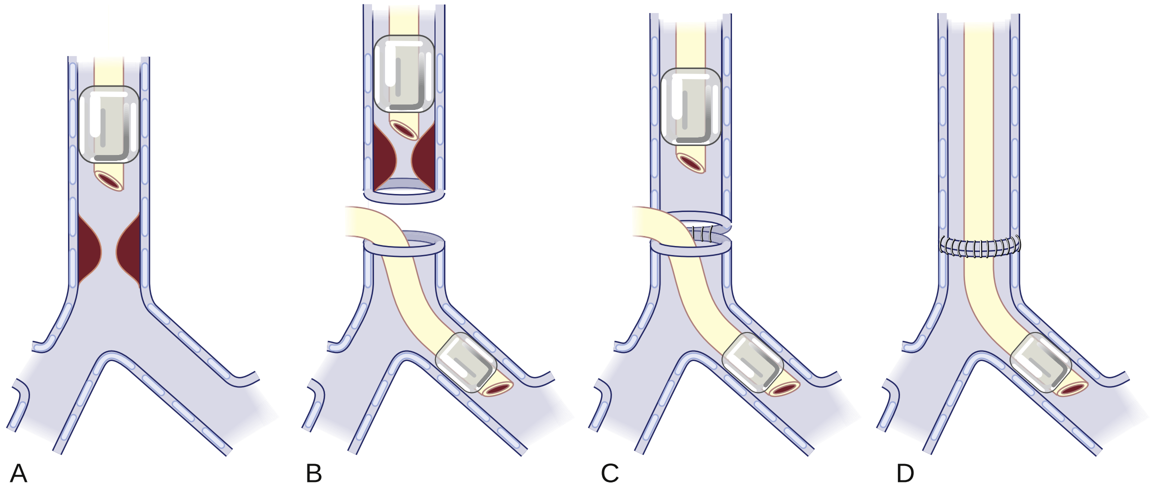

Fig. 53.50 Airway management and surgical procedure for resection of a low tracheal lesion. (A) Initial intubation above the lesion. (B) Left endobronchial intubation distal to the lesion after the trachea has been opened. (C) Placement of sutures for the posterior anastomosis. (D) The endobronchial tube has been removed, and the original endotracheal tube has been advanced distal to the anterior anastomosis into an endobronchial position. (Modified from Geffin B, Bland J, Grillo HC. Anesthetic management of tracheal resection and reconstruction. *Anesth Analg*. 1969;48:884.)

tracheal tumor, previous tracheal trauma (most commonly due to postintubation stenosis), congenital anomalies, vascular lesions, and tracheomalacia. For patients who have operable tumors, approximately 80% undergo segmental resection with primary anastomosis, 10% undergo segmental resection with prosthetic reconstruction, and the remaining 10% undergo placement of a T-tube stent.

Diagnostic studies are reviewed as part of the preoperative evaluation. The CT scan is a useful diagnostic tool to evaluate the degree, level, and length of the lesion. Bronchoscopy is one of the definitive diagnostic tests for tracheal obstruction. Bronchoscopy for a patient with tracheal stenosis should be carried out in the operating room where the surgical and anesthesia teams are present and ready to intervene should loss of airway occur. An advantage of rigid bronchoscopy over flexible bronchoscopy is that it can bypass the obstruction and provide a ventilation pathway if complete obstruction occurs. During surgery, all patients should have an invasive arterial catheter placed to facilitate measurement of arterial blood gases, as well as measure arterial blood pressure. CVP catheters are only used if the patient requires cardiopulmonary bypass (CPB).

A variety of methods for providing adequate oxygenation and elimination of CO_2 have been used during tracheal resection. The different alternatives include: (1) standard orotracheal intubation, (2) insertion of a sterile SLT into the opened trachea or bronchus distal to the area of resection, (3) HFJV through the stenotic area, (4) HFPPV, and (5) the use of ECMO.

Induction of anesthesia in patients with a compromised airway requires good communication between the surgical team and the anesthesiologist. The surgeon should always be in the operating room during induction and available to manage a surgical airway if this becomes necessary.[254] A rigid bronchoscope must be immediately available. The patient should be thoroughly preoxygenated with 100% oxygen before induction. The airways of patients with congenital or acquired tracheal stenosis are unlikely to collapse during induction of anesthesia. However, intratracheal masses may lead to airway obstruction with induction of anesthesia and should be managed similarly to anterior mediastinal masses (discussed later in chapter). One airway management technique is to begin the case with rigid bronchoscopy and tracheal dilation and then to pass an SLT through the stenosis. This tube is withdrawn into the proximal trachea once the distal trachea is opened and a second sterile SLT is placed into the distal trachea by the surgeon. Ventilation is done via a sterile anesthetic circuit with an airway gas sampling catheter passed across the drapes into the surgical field (this technique is commonly referred to a "cross-field ventilation"). With a low tracheal lesion, a right thoracotomy provides the optimal surgical exposure. A sterile SLT is used to provide ventilation to the lung distal to the resection. After the posterior anastomosis is completed, the endobronchial tube is removed and the original SLT is advanced past the site of resection (Fig. 53.50). This technique can also be used for carinal resection.

A third technique for airway management during tracheal resection includes HFJV through a small-bore ETT or catheter.[255] With this technique, a small-bore uncuffed catheter is placed through the stenotic area, and ventilation is accomplished by intermittently exposing the lung to a high flow of fresh gas through the catheter. Other techniques that have been used for oxygenation during distal airway resections include HFPPV, helium-oxygen mixtures, and CPB.

After the tracheal resection is completed, most patients are kept in a position of neck flexion to reduce tension on the suture line. Replacement of the SLT by an LMA for emergence facilitates bronchoscopy if required. A thick chin-sternum suture may be placed for several days to maintain neck flexion or a cervical splint may be used.[256] A Montgomery T-tube with the upper limb 0.5 to 1 cm above the vocal cords may be inserted at the end of surgery as a tracheal stent in cases when glottic edema is a concern, or for patients requiring ventilatory support. If a tracheostomy is performed, it will be done distal to the anastomosis. Early extubation is highly desirable. If a patient requires reintubation, it should be performed with a flexible fiberoptic bronchoscope by advancing an SLT under direct vision over

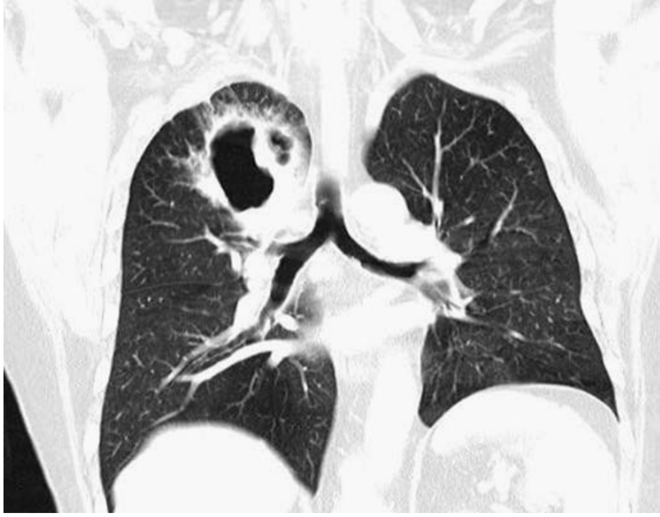

Fig. 53.51 Computed tomographic scan of a patient with a lung abscess distal to an obstructing carcinoma of the right upper lobe. The diagnostic thick wall of the abscess and the air-fluid level can be appreciated in the right upper thorax. These patients are at risk for soiling of uncontaminated lung regions during repositioning for surgery from pus in the abscess. The optimal method of lung isolation is with a double-lumen endobronchial tube.

the bronchoscope and then placing it in the patient's trachea. The patient is kept in a head-up position to diminish swelling. Steroids may be useful in these cases to decrease airway edema.

One of the complications in the postoperative period is tetraplegia, with hyperflexion of the neck having been implicated as a potential cause. In these cases, it is necessary to cut the chin stitch. Infusions of propofol/remifentanil or dexmedetomidine, with fiberoptic bronchoscopy guidance and full patient cooperation, can aid extubation.[257]

BRONCHIECTASIS/LUNG ABSCESS/EMPYEMA

Bronchiectasis is a disease that causes localized, irreversible dilatation of part of the bronchial tree. Involved bronchi are inflamed and easily collapsible, resulting in airflow obstruction and impaired clearance of secretions. Bronchiectasis is associated with a wide range of disorders, but it usually results from necrotizing bacterial infections. Bronchiectasis may require surgery if it causes hemoptysis or recurrent pneumonia. An abscess is a nonanatomic area of liquefactive necrosis of the lung often distal to an obstruction or following a pneumonia (Fig. 53.51). An empyema is a collection of pus between the visceral and parietal pleural layers often a complication of pneumonia or surgery. Empyema complicating lung resections occurs in 2% to 16% of cases and with a 40% increase in the associated perioperative mortality rate. Mortality further increases when the empyema is associated with a bronchopleural fistula. Surgical interventions for patients with empyema include decortication (the method of choice when the underlying lung is unable to expand because of a thick inflammatory coat) or open-window thoracostomy (the ideal method for drainage of the pleural cavity to control septic symptoms in patients with postpulmonary resection empyema).[258] In less severe cases, tube drainage, antibiotic irrigation, and debridement may be sufficient.

All of these infective indications for thoracic surgery are less common in the developed world since the introduction of antibiotics. Anesthetic considerations during surgery for these infective indications include the need for lung isolation to protect uninvolved lung regions from soiling by pus in the infected areas. The risk of soiling occurs if the patient is repositioned for surgery, after induction of anesthesia, before the lung is adequately isolated. Because of the inflammation, surgery is technically more difficult and there is a greater risk of massive hemorrhage.

Anesthetic Management

Some of these patients may present with sepsis at the time of surgery. In septic patients, the placement of a thoracic epidural catheter is not recommended. These patients require lung isolation, preferably with a DLT. The DLT facilitates suctioning of debris and copious secretions that are present in the tracheobronchial tree. Patients undergoing a decortication may have massive blood loss. If the lung has been chronically collapsed, expansion should be done gradually to avoid the development of pulmonary edema upon reexpansion. Extubation in the operating room is encouraged if the patient meets standard criteria for extubation.

BRONCHOPLEURAL FISTULA

A bronchopleural fistula may be caused by: (1) rupture of a lung abscess, bronchus, bulla, cyst, or parenchymal tissue into the pleural space; (2) the erosion of a bronchus by carcinoma or chronic inflammatory disease; or (3) stump dehiscence of a bronchial suture line after pulmonary resection. Pneumonectomy patients have an incidence of bronchopleural fistula ranging from 2% to 11%,[259] with mortality ranging from 5% to 70%.

The diagnosis of bronchopleural fistula is usually made clinically. After pneumonectomy, the diagnosis is based on the sudden onset of dyspnea, subcutaneous emphysema, contralateral deviation of the trachea, and a decrease of fluid level on serial radiographs of the chest (Fig. 53.52). In lobectomy patients, persistent air leak, purulent drainage, and expectoration of purulent material are usually diagnostic indicators of a bronchopleural fistula. When the fistula appears after removal of a chest tube, the diagnosis of bronchopleural fistula is made on the basis of fever, purulent sputum, and a new air-fluid level in the pleural cavity on the chest radiograph.

The diagnosis is confirmed by bronchoscopic examination. Additionally, bronchography and sinograms of the fistula may be used to confirm the diagnosis. Other diagnostic methods include the injection of an indicator, such as methylene blue, into the pleural space and subsequent recovery of the indicator from sputum. Accumulation of radionuclide in the pleural space after inhalation of xenon or a mixture of O_2 and N_2O to detect the presence of a bronchopleural fistula can also be used as indicators.[260]

If the disruption occurs early in postpneumonectomy patients, it can be life threatening and it is possible to resuture the stump. Late or chronic postpneumonectomy bronchial disruption is managed with drainage or with the Clagett procedure, which includes open pleural drainage and the use of a muscle flap to reinforce the bronchial stump. In nonpneumonectomy cases, if the lung expands to

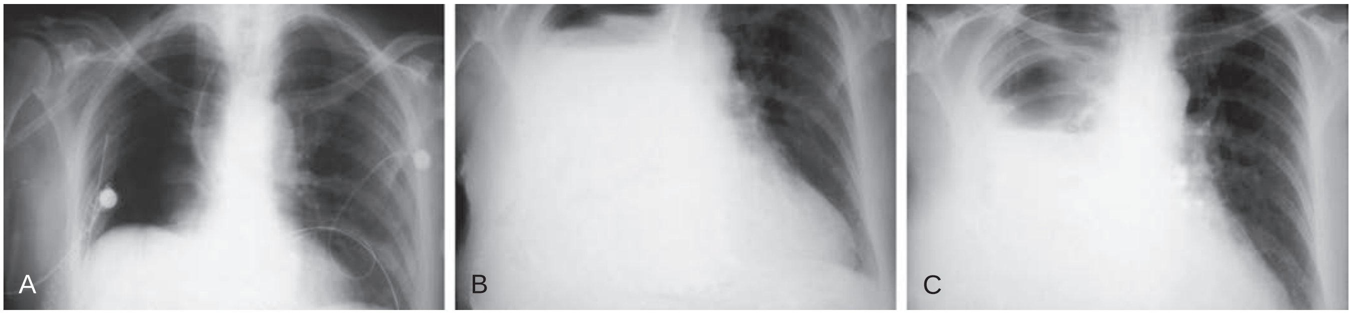

Fig 53.52 (A) Chest radiograph of a patient immediately postoperatively after a right pneumonectomy. (B) The same patient on postoperative day 6. This is a normal postpneumonectomy film. The right hemithorax is gradually filling with serous fluid. (C) The same patient on postoperative day 7. The patient had the sudden onset of severe dyspnea, desaturation, and coughing. The chest radiograph reveals a decrease in the fluid level in the right hemithorax. This is diagnostic of a bronchopleural fistula caused by the dehiscence of the bronchial stump.

fill the thoracic cavity, the air leak can usually be controlled with chest tube drainage alone. However, if the fistula is large and a significant leak through a large persistent pleural space occurs, it is unlikely that the fistula will close, and surgical resection is necessary.

Anesthetic Management

The patient with a bronchopleural fistula presents several intraoperative challenges for the anesthesiologist. These include: (1) the need for lung isolation to protect healthy lung regions, (2) the possibility of tension pneumothorax with positive-pressure ventilation, and (3) the possibility of inadequate ventilation due to air leak from the fistula. Preoperatively, it is useful to estimate the loss of tidal volume through the bronchopleural fistula, which may be done in two ways. First, one should determine whether air bubbles flow intermittently or continuously through the chest tube. If air bubbles flow intermittently, then the fistula is small. In contrast, when a patient has a large bronchopleural fistula or bronchial rupture, air will bubble continuously through the water-seal chamber of the chest-tube drainage system. Second, the size of the bronchopleural fistula may be quantified by the difference between inhaled and exhaled tidal volumes. In a nonintubated patient, this may be determined with a tight-fitting mask and a fast-responding spirometer. In an intubated patient, it is determined by direct attachment of the spirometer to the ETT. The larger the air leak, the greater the need to isolate the bronchopleural fistula with the use of a lung isolation device (a DLT or an independent bronchial blocker).

Several nonsurgical approaches (i.e., the use of various mechanical ventilation–chest tube drainage systems) have been used for the treatment of patients with a bronchopleural fistula. These approaches consist of OLV and differential lung ventilation, including HFV, PEEP to the pleural cavity equal to intrathoracic PEEP, and unidirectional chest tube valves. One-way endobronchial valves have been used successfully in patients with bronchopleural fistula who were considered unfit for surgery.[261]

For patients undergoing operative repair, the ability to adequately deliver positive-pressure ventilation intraoperatively must be carefully considered prior to surgery. A chest drain should be placed prior to induction to avoid the possibility of tension pneumothorax with positive-pressure ventilation. A DLT is the best choice for delivering positive-pressure ventilation. The DLT can provide positive-pressure ventilation to the normal lung without loss of minute ventilation through the fistula and prevent the hazard of contamination of the uninfected lung with infected material when the patient is turned to the lateral decubitus position.

The safest method of obtaining lung isolation may be awake fiberoptic intubation with a DLT.[262] However, this requires a cooperative patient and excellent topical anesthesia and is often not an option. Another option is to maintain spontaneous ventilation during induction and intubation until lung isolation is secured. This avoids the possibility of inadequate positive-pressure ventilation because of air-leak but is not well tolerated in older patients with significant comorbidity. With the availability of appropriate fiberoptic bronchoscopes, it is usually acceptable to manage patients with a normal airway using a modified rapid-sequence induction and direct bronchoscopic guidance of the DLT placement. If the patient has a postpneumonectomy fistula, the endobronchial lumen of the DLT or SLT should be placed in the noninvolved lung (i.e., for right-sided fistula a left-sided tube). Whatever anesthetic technique is used, the principle of anesthetic management for a bronchopleural fistula is: lung isolation must be confirmed before positive-pressure ventilation or repositioning the patient.

One option to avoid instrumentation of the airway in patients with bronchopleural fistula after pneumonectomy is the use of thoracic epidural anesthesia with intravenous sedation during minimally invasive surgery (discussed later in "Nonintubated Thoracic Surgery").[263] An alternative method of ventilating patients with multiple bronchopleural fistulas is the use of high-frequency oscillatory ventilation with permissive hypercapnia. This avoids barotrauma to the nonoperative lung, decreases bronchopleural fistula air-leak, and optimizes the operative outcome.[264] The advantage of high-frequency oscillatory ventilation over conventional mechanical ventilation is that it uses lower peak airway pressure and higher minimum airway pressure and may decrease the air leak across the fistula. Early extubation in the operating room should be considered in all patients undergoing fistula repair to avoid barotrauma to the surgical stump from positive-pressure ventilation in the postoperative period.

A report of two cases described the use of venovenous ECMO in a patient with an existing left bronchopleural fistula and thoracostomy who required a right thoracotomy for tumor resection (left lung ventilation and right lung collapse).[265] ECMO was initiated prior to OLV to maintain oxygenation during lung collapse.

Blebs, Bullae, Cysts, and Pneumatoceles

BLEBS

A bleb is a subpleural collection of air under the visceral pleura caused by a ruptured alveolus. The air dissects through the pulmonary parenchyma and enlarges to form a bubble on the surface of the lung. Blebs most commonly occur at the apices of the lung and can rupture into the interpleural space, causing a pneumothorax. A single episode of spontaneous pneumothorax is usually treated conservatively with chest tube drainage until the air leak has stopped. Resection of blebs is commonly indicated for recurrent pneumothoraces, bilateral pneumothoraces, or prolonged chest tube drainage. Resection of blebs after a single pneumothorax may be indicated if the patient's occupation exposes them to significant rapid fluctuations in atmospheric pressure (e.g., flight crews or scuba divers). Resection is most commonly combined with a procedure to obliterate the pleural space by partial pleurectomy or pleural abrasion. Resection of blebs is most often performed by VATS. Although VATS procedures per se are generally associated with a limited need for postoperative analgesia, pleurectomy or abrasion can be very painful.

BULLAE

Bullae are thin-walled, air-filled intraparenchymal lung spaces caused by the loss of alveolar structural tissue (Fig. 53.53). These are usually associated with emphysema, but their exact cause is unclear. Although there is some confusion over terminology in this area, bullous-like lesions of the lung associated with congenital malformations or secondary to trauma or infection are more correctly termed pneumatoceles or cysts. There are no universally accepted surgical indications for resection of lung bullae. A patient with symptomatic dyspnea and a giant bulla (or bullae) that occupies more than 30% of a hemithorax and in whom radiography and CT scans suggest that reasonably functional lung tissue can be restored to a more anatomically favorable position should be considered for bullectomy. Factors that support the effect of the bullae as a cause of a patient's dyspnea are a restrictive pattern of spirometry (proportional decrease of both FEV_1 and FVC) and a discrepancy in lung volume studies in which the FRC measured by plethysmography exceeds the FRC measured by helium dilution by more than 2 liters.

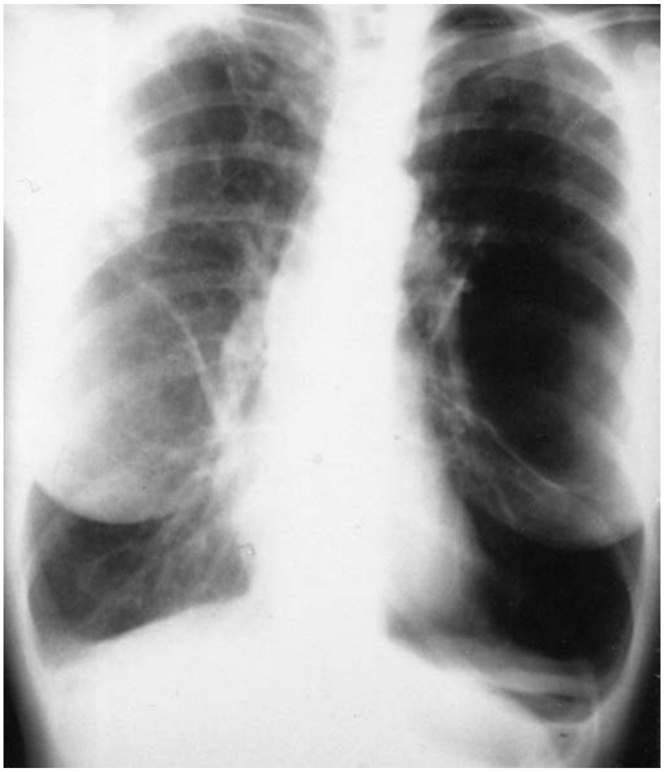

Fig. 53.53 Chest radiograph of a patient with severe emphysema and multiple bullae including giant bullae of the left upper and lower lobes. This patient also has a carcinoma of the right upper lobe.

In the usual tidal volume range, bullae are more compliant than normal lung and fill preferentially during spontaneous ventilation. However, beyond the normal tidal volume range, bullae become much less compliant and the intrabulla pressure rises acutely as airway pressure increases. Measurement of in vivo intrabullae pressures in patients using fine needles both before and during anesthesia showed no evidence of a valve mechanism.[60] All bullae studied communicated with the central airways, although some very slowly. The typical compression pattern seen on radiographs or CT scans is most likely due to secondary elastic recoil of normal lung regions (see Fig. 53.9). Intrabulla pressure at FRC corresponds with the mean airway pressure averaged over the respiratory cycle. Thus during spontaneous ventilation, the intrabulla pressure will be negative with respect to the surrounding lung tissue. However, whenever positive pressure is used, the intrabulla pressure will rise in relation to surrounding lung regions. There is a risk of hyperinflation and rupture whenever positive pressure is used. The complications of bulla rupture can be life threatening because of hemodynamic collapse from tension pneumothorax or inadequate ventilation owing to resultant bronchopleural fistulae.

Relief of dyspnea symptoms and improved pulmonary function are well documented in patients after resection of giant bullae with most patients showing an increase in FEV_1 of more than 0.3 L and excellent short-term improvement in quality of life, but with a decrease in improvement by 3 years.[266] Hypercapnia is not a contraindication to bullae resection. Lung infection must be meticulously treated preoperatively. Outcome depends on patient age, smoking history, and cardiac status. In the postoperative period lung air leaks are the major complication. The surgical approach can be by traditional sternotomy or by VATS. Laser resection may decrease the incidence of air leaks. Various nonsurgical thoracoscopic and bronchoscopic procedures such as the subsegmental injections of fibrin glue have been used to deal with these air leaks.

The anesthetic considerations for bullectomy are similar to those for a patient with a bronchopleural fistula, with the exceptions that it is best not to place a chest drain prophylactically as this may enter the bulla and create a fistula, and there is not the risk of soiling healthy lung regions from extrapleural fluid that there is with fistulae. For induction of anesthesia it is optimal to maintain spontaneous ventilation or to use small tidal volumes and low airway pressures until the lung or lobe with the bulla or bleb is isolated.[267] When there is a risk of aspiration or it is felt that the patient's gas exchange or hemodynamics may not permit spontaneous ventilation for induction, the anesthesiologist will have to use small tidal volumes and low airway pressures during positive pressure ventilation until the airway is isolated.

CYSTS

Congenital bronchogenic cysts are products of abnormalities in the tracheobronchial budding process of lung organogenesis. They may occur peripherally within the lung parenchyma (70%) or centrally attached to the mediastinum or hilum. Bronchogenic cysts become problematic if they become enlarged, exerting a mass effect on functional lung or mediastinal structures; if they rupture and create a pneumothorax; or if they become infected. Small cysts without communication to a bronchus are asymptomatic and may be incidentally noted as round, clearly demarcated lesions on chest radiographs. Communicating cysts often produce air-fluid levels, are prone to recurrent infection, and may trap air by a ball-valve mechanism, risking rapid expansion or rupture. Infected cysts may be obscured by surrounding pneumonia, or they may be difficult to differentiate from an empyema. CT scans help differentiate cystic from solid lesions. Conservative surgical excision of bronchogenic cysts is generally recommended, whether or not a bronchial communication is evident.

Pulmonary hydatid cysts are watery, parasitic cysts containing larvae of the dog tapeworm, *Echinococcus granulosus*.[268] *E. granulosus* is a relatively common cause of pulmonary cysts in endemic areas (Australia, New Zealand, South America, and some third-world regions). Hydatid cysts may grow in diameter by as much as 5 cm/year and become medically problematic in several ways. By mass effect, they may exert pressure on adjacent structures (e.g., bronchus, great vessels, esophagus). Spontaneous or traumatic rupture may occur, sending fluid, parasites, or laminated debris into adjacent tissue, bronchus, pleura, or the circulation (i.e., systemic emboli). Hypersensitivity reactions, bronchospasm, and anaphylaxis can result. Drainage into the bronchi may cause dramatic expulsion of fluid with respiratory distress or asphyxiation, depending on the amount of fluid involved. Rupture into the pleural space may result in a large hydropneumothorax, severe dyspnea, shock, suffocation, or anaphylaxis. Rupture becomes more dangerous and more likely as cysts become larger. It is recommended that any cyst larger than 7 cm should be removed.

Small, intact peripheral cysts are often easily enucleated without loss of lung parenchyma. Segmentectomy or lobectomy is indicated when single or multiple cysts occupy most of the segment or lobe. Patients with suppurative cysts should be prepared for surgery with postural drainage and antibiotics. Lung isolation and/or reduced airway pressure during dissection may be helpful in preventing herniation of the cyst. Increased airway pressure at the time of delivery may aid removal of the cyst. The multiple bronchial openings in the residual cavity must then be identified and closed. Multiple “leak tests” with saline in the residual opening may be required to locate all bronchial openings. An alternative surgical strategy is to inject hypertonic saline into the cyst to sterilize it, followed by aspiration of the contents and removal of the evacuated cyst.

PNEUMATOCELE

Pneumatoceles are thin-walled, air-filled spaces generated by pulmonary infections or trauma. They usually appear in the first week of a pneumonia and resolve spontaneously within 6 weeks. As with other lung cysts, potential complications of pneumatoceles include secondary infection and enlargement as a result of air entrapment, with possible rupture or displacement and compression of normal lung. Adverse hemodynamic consequences may result either from a tension pneumothorax or a tension pneumatocele. The latter is unusual and is presumed to result from a one-way valve mechanism, usually in the setting of positive-pressure mechanical ventilation.[269] Occasionally, surgical decompression is required and is performed by percutaneous needle aspiration, catheter drainage, or chest tube drainage under CT or fluoroscopic guidance. Rarely is thoracoscopic or open surgical drainage or excision required.

Lung Transplantation

End-stage pulmonary disease is one of the most common causes of death. Lung transplantation is a definitive treatment for these patients. Indications and contraindications to lung transplantation are summarized in Box 53.15. Approximately 1500 lung transplantations are performed annually worldwide; the number is limited by the supply of donor organs. Recipients fall into four major categories (by frequency of indication):

1. Pulmonary fibrosis: idiopathic, associated with connective tissue disorders, other
2. COPD
3. Cystic fibrosis (Fig. 53.54) and other congenital forms of bronchiectasis
4. Primary pulmonary hypertension

There are also several other, rarer indications such as primary bronchoalveolar lung cancer, lymphangioleiomyomatosis, and so on.[270] Depending on the patient's pathophysiology, there are several surgical options: single-lung transplantation, bilateral sequential (double) lung transplantation, heart-lung transplantation, and living-related lobar transplantation. An overall 5-year survival rate of 50% is the benchmark but depends on recipient age and diagnosis. Survival is generally better with double-lung than single-lung transplants, with the exception of elderly pulmonary fibrotic patients, for whom there is no outcome difference between the two procedures.

Anesthetic airway management is most commonly done with a DLT. The advantage of using a DLT in transplantation is that it allows direct continuous access to both lungs for suctioning, oxygenation, and examination of the bronchial anastomoses. Several advances have allowed the use of DLTs for transplantation. The use of segmental bronchial lavage at induction via an SLT, before placement of the DLT, facilitates suctioning via the DLT in patients with copious secretions. Monitoring

BOX 53.15 **Indications and Contraindications for Lung Transplantation**

Indications

Untreatable end-stage pulmonary, parenchymal, and/or vascular disease
Absence of other major medical illnesses
Substantial limitation of daily activities
Projected life expectancy less than 50% of 2- to 3-year predicted survival
New York Heart Association Class III or IV functional level
Rehabilitation potential
Satisfactory psychosocial profile and emotional support system
Acceptable nutritional status
Disease-specific mortality exceeding transplant-specific mortality over 1 to 2 years

Relative Contraindications

Over 65 years of age
Critical or unstable clinical conditions (e.g., shock, mechanical ventilation, or extracorporeal membrane oxygenation)
Severely limited functional status with poor rehabilitation potential
Colonization with highly resistant or virulent bacteria, fungi, or mycobacteria
Severe obesity defined as a body mass index greater than 30 kg/m^2
Severe or symptomatic osteoporosis
Other medical conditions not resulting in end-organ damage (e.g., diabetes mellitus, systemic hypertension, peripheral vascular disease, gastroesophageal reflux, patients with coronary artery disease s/p coronary artery stenting or percutaneous transluminal coronary angioplasty)

Absolute Contraindications

Untreatable advanced dysfunction of another major organ system (e.g., heart, liver, kidney)
Active malignancy within the previous 2 years
Noncurable chronic extrapulmonary infection
Chronic active viral hepatitis B, hepatitis C, or HIV
Significant chest wall or spinal deformity
Documented nonadherence or inability to follow through with medical therapy, office follow-up, or both
Untreatable psychiatric or psychologic condition associated with inability to cooperate or comply with medical therapy
Absence of a consistent or reliable social support system
Substance addiction (e.g., alcohol, tobacco, narcotics) that is either active or was active within the previous 6 months

Based on Weill D, et al. *J Heart Lung Transplant*. 2015;34:1.

includes invasive arterial and pulmonary catheters and TEE in most centers. Anesthetic maintenance is based mainly on intravenous infusions because of the frequent need for airway access (i.e., suctioning, bronchoscopy), which causes problems maintaining a stable level of inspired anesthetic vapor. In spite of advances in lung preservation techniques, it is optimal to limit the donor lung ischemic period to 4 hours.

There are wide site-specific variations in the use of ECMO and CPB during lung transplantation. For adults, intraoperative venoarterial ECMO is largely replacing CPB due to the decreased need for blood transfusions and improved postoperative outcomes.[271] Venovenous ECMO is used increasingly for postoperative respiratory support.

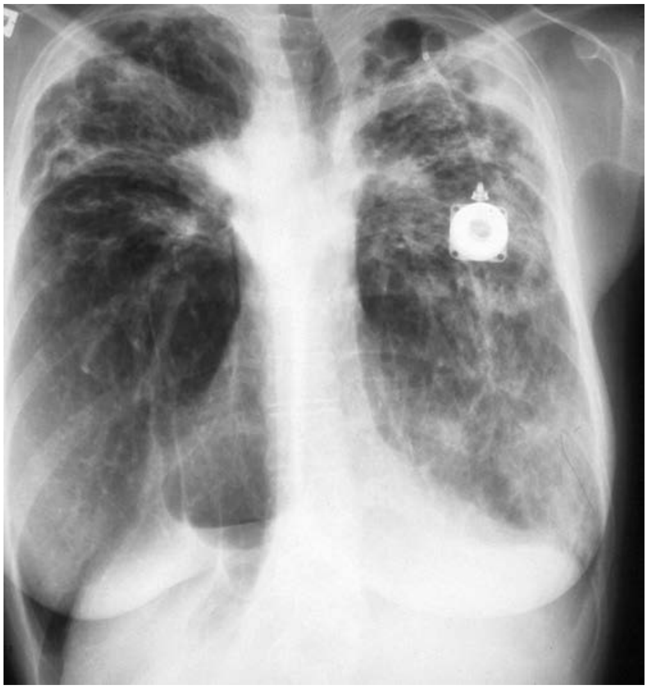

Fig. 53.54 Chest radiograph of a patient with cystic fibrosis for bilateral lung transplantation. The chest image shows a typical pattern of bronchiectasis. A subcutaneous intravenous injection reservoir is seen over the upper left chest.

The intraoperative anesthetic complications depend, in large part, on the underlying lung disease. Emphysema patients are prone to hypotension on induction from positive-pressure ventilation (see COPD in “Preoperative Evaluation of the Thoracic Surgery Patient” earlier). Problems in cystic fibrosis patients include the inability to deal with thick bronchial secretions and to adequately ventilate these patients. Cystic fibrosis patients, because they have both increased inspiratory and expiratory flow resistances, may benefit from slow inspiratory phase ventilation with a high airway pressure.[272] Because of the severely decreased lung compliance, this method of ventilation causes little hemodynamic compromise in this subgroup of patients, if air trapping is avoided. Other recipient disease-specific problems include: hemodynamic collapse on induction because of right-heart dysfunction in primary pulmonary hypertensives, the poor tolerance of pulmonary fibrotic patients for OLV, and the risk of pneumothoraces in patients with lymphangiomyomatosis.

ANESTHESIA FOR THE PATIENT AFTER LUNG TRANSPLANTATION

Many lung transplant recipients subsequently require anesthesia for related, or unrelated, surgical problems.[273] The frequency with which they present for surgery may be caused by complications of immunosuppression (e.g., infection, tumor, renal failure) or complications of the transplantation (e.g., bronchial stenosis, bronchiolitis obliterans).

A review of the patient’s prior spirometry and diffusion capacity tests should be carried out to identify patients who have low pulmonary reserve. Bronchiolitis obliterans syndrome (BOS) is a chronic rejection disorder seen in many post–lung transplant patients that leads to a restrictive lung disease. BOS accounts for a considerable proportion of the deterioration in lung function and affects more than half of the recipients that survive beyond 5 years. It is the main cause of mortality in patients who survive more than a year.[274]

Most transplant recipients can be managed according to routine anesthetic practice including optimal perioperative respiratory care, antibiotic prophylaxis, and maintenance of immune suppression. Results of recent blood gas analysis, chest radiographs, and CT scans are vital in managing these patients. Most adults will have bronchial anastomoses and there will be no problem with endotracheal intubation. If endobronchial intubation or a DLT is used, a bronchoscopy should be performed first to assess the bronchial anastomoses, and the intubation should be with fiberoptic guidance.

Single-lung transplant recipients with native lung emphysema are a specific concern. They have a marked imbalance in pulmonary compliance, with the native lung highly compliant and the donor lung of normal or reduced (if there is rejection) compliance. However, the major proportion of the pulmonary blood flow is usually to the allograft. With standard methods of positive pressure ventilation they may develop dynamic hyperinflation of the emphysematous lung with hemodynamic instability and problems with gas exchange. These patients may require the use of a DLT and independent lung ventilation techniques, reducing the airway pressure and minute ventilation in the native lung, if positive pressure ventilation is required.

LUNG VOLUME REDUCTION

The use of multiple wedge resections can reduce lung volume and improve symptoms in selected severe emphysema patients.[275] Depending on the patient and center, this procedure may be unilateral or bilateral and performed by thoracotomy, sternotomy, or VATS. The surgery is more effective in patients with heterogeneous lung disease where the most severely affected areas (often apical) can be resected, than in patients with homogenous types of emphysema (e.g., Alpha-1 antitrypsin deficiency). Patients with extremely severe disease (FEV_1 or DLCO < 20% predicted) have poor survival after surgery.[276] This procedure is now most commonly seen as an option for patients with severe emphysema who have contraindications to transplantation.

Immediate postoperative improvements in symptoms and pulmonary function are common, and many patients are able to discontinue or reduce home oxygen therapy. These changes are the result of a decompression of the airways and a reduction of airflow resistance and work of breathing,[277] which results in a dramatic fall in auto-PEEP (intrinsic PEEP) with a corresponding increase in dynamic compliance. Despite the encouraging changes in early postoperative pulmonary function, the improvement in respiratory function as a result of this surgery is transient.[278] However, this must be viewed in the context of the short life expectancy of patients with this degree of emphysema and the potential for improvement in their quality of life from the operation.

Anesthetic management is similar to that for other patients with severe COPD having thoracic surgery (see COPD in "Preoperative Evaluation of the Thoracic Surgery Patient" earlier) with the risk of hypotension on induction caused by auto-PEEP and the need for excellent analgesia to avoid postoperative mechanical ventilation.[279] This procedure is now performed in some centers using one-way valves or coils placed bronchoscopically in the most involved segments to cause collapse of severely emphysematous distal lung regions,[280] thus avoiding surgery.

Pulmonary Hemorrhage

Massive hemoptysis is defined as expectoration of more than 200 mL of blood in 24 to 48 hours. The most prevalent causes are carcinoma, bronchiectasis, and trauma (e.g., blunt, penetrating, or secondary to a pulmonary artery catheter). Death can occur quickly as a result of asphyxia. Management requires four sequential steps: lung isolation, resuscitation, diagnosis, and definitive treatment. The anesthesiologist is often called to deal with these cases outside of the operating room. There is no consensus on the best method of lung isolation for these cases. The initial method for lung isolation will depend on the availability of appropriate equipment and an assessment of the patient's airway. All three basic methods of lung isolation have been used: DLTs, SLTs, and bronchial blockers. Fiberoptic bronchoscopy is usually not helpful to position endobronchial tubes or blockers in the presence of torrential pulmonary hemorrhage and lung isolation must be guided by clinical signs (primarily auscultation). DLTs will achieve rapid and secure lung isolation. Even if a left-sided tube enters the right mainstem bronchus, only the right upper lobe will be obstructed. However, suctioning large amounts of blood or clots is difficult through the narrow lumens of a DLT. An option is initial placement of an SLT for oxygenation and suctioning then replacement with a DLT either by laryngoscopy or with an appropriate tube exchanger. An uncut single-lumen ETT can be advanced directly into the right mainstem bronchus or rotated 90 degrees counterclockwise for advancement into the left mainstem bronchus.[281] A bronchial blocker will normally pass easily into the right mainstem bronchus and is useful for right-sided hemorrhage (90% of pulmonary artery catheter-induced hemorrhages are right-sided). Except for cases with blunt or penetrating trauma, after lung isolation and resuscitation have been achieved, diagnosis and definitive therapy of massive hemoptysis are now most commonly performed by coiling of the pulmonary artery false aneurysm in invasive radiology.[282]

PULMONARY ARTERY CATHETER-INDUCED HEMORRHAGE

Hemoptysis in a patient with a pulmonary artery catheter must be assumed to be caused by perforation of a pulmonary vessel by the catheter until proven otherwise. The mortality rate may exceed 50%. This complication seems to be occurring less than previously, possibly related to stricter indications for the use of pulmonary artery catheters and more appropriate management of the catheters with less reliance on wedge measurements. Therapy for pulmonary artery catheter-induced hemorrhage should follow an organized protocol with some variation depending on the severity of the hemorrhage (Box 53.16).

BOX 53.16 Management of the Patient With a Pulmonary Artery Catheter

Induced Pulmonary Hemorrhage

1. Initially position the patient with the bleeding lung dependent.
2. Perform endotracheal intubation, oxygenation, airway toilet.
3. Isolate the lung by endobronchial double- or single-lumen tube or bronchial blocker.
4. Withdraw the pulmonary artery catheter several centimeters, leaving it in the main pulmonary artery. Do not inflate the balloon (except with fluoroscopic guidance).
5. Position the patient with the isolated bleeding lung nondependent. Administer positive end-expiratory pressure to the bleeding lung if possible.
6. Transport the patient to medical imaging for diagnosis and embolization if feasible.

During Weaning from Cardiopulmonary Bypass

Weaning from CPB is one of the times when pulmonary artery catheter-induced hemorrhage is most likely to occur. Management of the pulmonary artery catheter during CPB by withdrawal from a potential wedge depth and observing the pulmonary artery pressure waveform to avoid wedging during CPB may decrease the risk of this complication. When hemoptysis occurs during CPB weaning, the anesthesiologist should resist the temptation to rapidly reverse the anticoagulation in order to quickly discontinue CPB, because this can lead to fatal asphyxiation from hemorrhage. Resumption of full CPB ensures oxygenation while the tracheobronchial tree is suctioned and then visualized with fiberoptic bronchoscopy. The use of a pulmonary artery vent may be required to decrease the pulmonary blood flow sufficiently to define the bleeding site (usually the right lower lobe). The pleural cavity should be opened to assess the lung parenchymal damage. Conservative management with lung isolation, to avoid lung resection, is optimal therapy if possible. In patients with persistent hemorrhage who are not candidates for lung resection, temporary lobar pulmonary artery occlusion with a vascular loop during and after weaning from CPB may be an option.

Posttracheostomy Hemorrhage

Hemorrhage in the immediate postoperative period following a tracheostomy is usually from local vessels in the incision such as the anterior jugular or inferior thyroid veins. Massive hemorrhage 1 to 6 weeks postoperatively is most commonly caused by tracheoinnominate artery fistula.[283] A small sentinel bleed occurs in most patients before a massive bleed. The management protocol for tracheoinnominate artery fistula is outlined in Box 53.17.

BOX 53.17 Management of Tracheoinnominate Artery Fistula Hemorrhage

- Overinflate the tracheostomy cuff to tamponade the hemorrhage.
- If this fails:
  - Replace the tracheostomy tube with an oral endotracheal tube. Position the cuff with fiberoptic bronchoscopic guidance just above the carina.
  - Apply digital compression of the innominate artery against the posterior sternum using a finger passed through the tracheostomy stoma.
- If this fails:
  - Slowly withdraw the endotracheal tube and overinflate the cuff to tamponade.
  - Proceed with definitive therapy: sternotomy and ligation of the innominate artery.

Pulmonary Thromboendarterectomy

Pulmonary thromboendarterectomy is a potentially curative procedure for chronic thromboembolic pulmonary hypertension (CTEPH). CTEPH is a progressive disorder that responds poorly to conservative therapy, and pulmonary thromboendarterectomy is the most appropriate treatment, with a perioperative mortality of approximately 4%, which is less than lung transplantation. The majority of patients with CTEPH present for medical evaluation late in the disease because many have not had an obvious episode of deep venous thrombosis or pulmonary embolus, and the progression of the disease is insidious. Patients present with severe dyspnea on exertion and signs of right-sided heart failure. Surgical candidates have hemodynamically significant pulmonary vascular obstruction (pulmonary vascular resistance >300 dynes/sec/cm^5), with potentially accessible proximal areas of thromboemboli.

An inferior vena cava filter is often placed prophylactically prior to surgery. Surgery is performed via a midline sternotomy with CPB with or without periods of deep hypothermic circulatory arrest (DHCA). Anesthetic management is essentially the same as for a patient with primary pulmonary hypertension for lung transplantation, with the exception that there is no need for lung isolation, so airway management is done with a standard ETT. Monitoring includes femoral and pulmonary artery catheters, TEE, processed electroencephalography, and rectal/bladder temperatures.[284]

These patients are at risk of hemodynamic collapse because of right ventricular failure from hypotension during induction of general anesthesia. Induction may be performed with etomidate or ketamine to avoid hypotension. Support of SVR with noradrenaline or phenylephrine is usually required. If DHCA is used, it is preceded by mannitol and methylprednisolone to try to decrease cerebral cellular edema and to improve free-radical scavenging. The speed of warming and cooling is controlled on CPB to maintain a temperature gradient less than 10°C between blood and bladder/rectal temperatures. Periods of DHCA are usually limited to 20 minutes. Massive pulmonary hemorrhage occurs rarely during CPB in these cases. The instillation of phenylephrine 10 mg and vasopressin 20 units diluted in 10 mL saline via the ETT may be beneficial. Postoperatively, the patients are kept sedated, intubated, and ventilated for at least 24 hours to decrease the risk of reperfusion pulmonary edema. Noradrenaline or vasopressin infusions may be used to elevate the SVR and decrease cardiac output in order to decrease pulmonary blood flow.

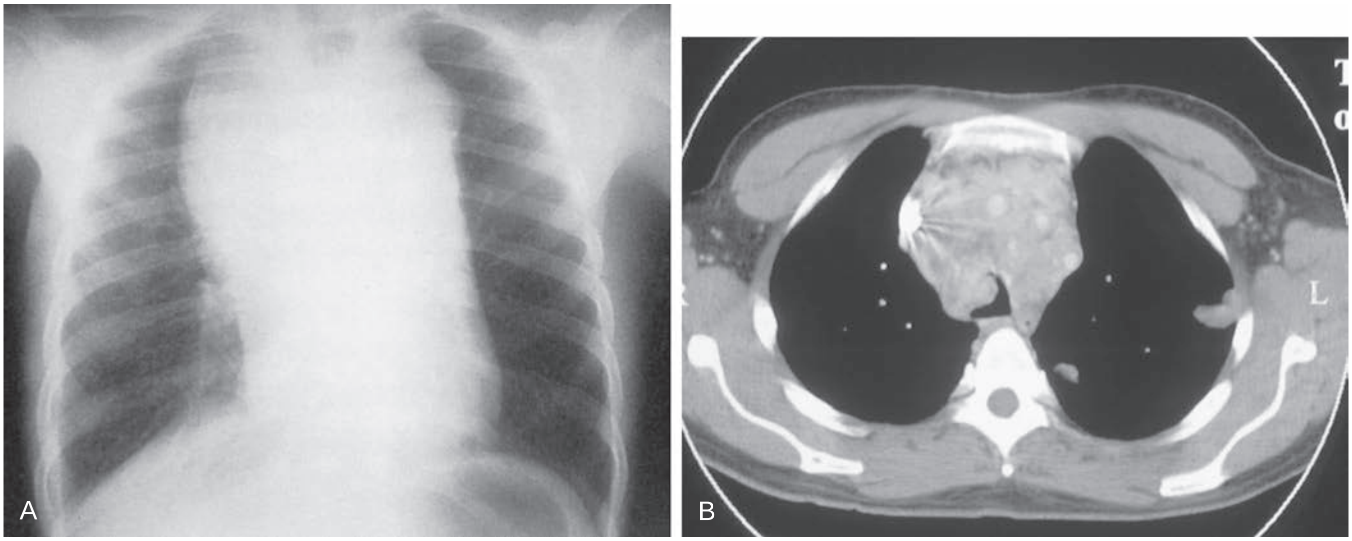

Fig. 53.55 (A) Chest radiograph of an adult patient with an anterosuperior mediastinal mass. This mass was a lymphoma. (B) A thoracic computed tomographic scan with contrast just above the level of the carina shows partial compression of the carina and right mainstem bronchus. This patient has an "Uncertain" distal airway (see text).

Bronchopulmonary Lavage

Bronchopulmonary lavage (BPL) is a treatment during which up to 10 to 20 L of normal saline are instilled then drained in 500- to 1000-mL aliquots through one side of a DLT into one lung under general anesthesia until the effluent is clear.[285] It may then be performed on the contralateral lung during the same anesthetic or during a subsequent anesthetic after a period of several days for recovery. It is the most effective treatment modality for symptomatic pulmonary alveolar proteinosis. This lung disease results from accumulation in the alveoli of a lipoprotein material similar to surfactant.[286] This disease seems to have an immune component, and some patients respond to conservative medical therapy with granulocyte-macrophage colony-stimulating factor.[287] Other pathologic states that have been treated by BPL include cystic fibrosis, asthma, radioactive dust inhalation, lipoid pneumonitis, and silicosis, all without convincing success.

General anesthesia is induced and maintained with intravenous infusions as for lung transplantation. Airway management is with a left-sided DLT.[288] The patient is kept in the supine position during the procedure. Because of transmitted hydrostatic pressure from the lavage lung to the pulmonary circulation, oxygenation increases during the filling phase and decreases during the emptying phase in synchrony with changes in the pulmonary blood flow distribution. These changes are usually transient and well tolerated. Usually 10 to 15 L is instilled and more than 90% is recovered leaving a deficit of less than 10%. At the end of the procedure, the lavaged lung is thoroughly suctioned. A dose of furosemide (10 mg) is administered to increase diuresis of absorbed saline. If the plan is to proceed to a lavage of the contralateral lung, there is a period of at least 1 hour of TLV to allow recovery of the lavaged lung, during which arterial blood gases are monitored. If there is a persistent large alveolar-arterial oxygen gradient preventing lavage of the second lung, venovenous ECMO may be instituted or the patient can be brought back for lavage of the other lung at a later date. Postprocedure, after reintubation with an SLT, a fiberoptic bronchoscopic inspection is performed for suctioning. Conventional ventilation with PEEP is continued, usually for less than 2 hours. Observation in the intensive care unit for 24 hours is part of the routine procedure. Some patients require lavage every few months, whereas others remain in remission for years.

Mediastinal Masses

Patients with mediastinal masses, particularly masses in the anterior or superior mediastinum, or both, present unique problems for the anesthesiologist. Patients may require anesthesia for biopsy of these masses by mediastinoscopy or VATS, or they may require definitive resection via sternotomy or thoracotomy. Tumors of the mediastinum include thymoma, teratoma, lymphoma, cystic hygroma, bronchogenic cyst, and thyroid tumors . Mediastinal masses may cause obstruction of major airways, main pulmonary arteries, atria, and the superior vena cava. During induction of general anesthesia in patients with an anterior or superior mediastinal mass, airway obstruction is the most common and feared complication. It is important to note that the point of tracheobronchial compression usually occurs distal to an ETT (Fig. 53.55) and it may not be possible to forcibly pass an ETT through the airway once it has collapsed. A history of supine dyspnea or cough should alert the clinician to the possibility of airway obstruction upon induction of anesthesia. Life-threatening complications may occur in the absence of symptoms in children. The other major complication is cardiovascular collapse secondary to compression of the heart or major vessels. Symptoms of supine presyncope suggest vascular compression.

Anesthetic deaths have mainly been reported in children. These deaths may be the result of the more compressible cartilaginous structure of the airway in children or because of the difficulty in obtaining a history of positional symptoms in children. The most important diagnostic test in the patient with a mediastinal mass is the CT scan of the trachea and chest. Children with tracheobronchial compression greater than 50% on CT scan cannot be safely given general anesthesia.[289] Flow-volume loops, specifically the exacerbation of a variable intrathoracic obstructive pattern (expiratory plateau) when supine, are unreliable[290] for predicting which patients will have intraoperative airway collapse.[291] Transthoracic echocardiography is indicated for patients with vascular compression symptoms.

MANAGEMENT

General anesthesia will exacerbate extrinsic intrathoracic airway compression in three ways. First, reduced lung volume occurs during general anesthesia and tracheobronchial diameters decrease according to lung volume. Second, bronchial smooth muscle relaxes during general anesthesia allowing greater compressibility of large airways. And third, paralysis eliminates the caudal movement of the diaphragm seen during spontaneous ventilation. This eliminates the normal transpleural pressure gradient that dilates the airways during inspiration and minimizes the effects of extrinsic intrathoracic airway compression.

Management of these patients is guided by their symptoms and the CT scan (Boxes 53.18 and 53.19). Patients with "uncertain" airways should have diagnostic procedures performed under local or regional anesthesia whenever possible. Patients with "uncertain" airways requiring general anesthesia need a step-by-step induction of anesthesia with continuous monitoring of gas exchange and hemodynamics. This "NPIC" (*noli pontes ignii consumere*; i.e., "don't burn your bridges") anesthetic induction can be an inhalation induction with a volatile anesthetic such as sevoflurane or intravenous titration of propofol with or without ketamine, maintaining spontaneous ventilation until either the airway is definitively secured or the procedure is completed.[292] Awake intubation of the trachea before induction is a possibility in some adult patients if the CT scan shows an area of noncompressed distal trachea to which the ETT can be advanced before induction. If muscle relaxants are required, ventilation should first be gradually taken over manually to assure that positive-pressure ventilation is possible and only then can a short-acting muscle relaxant be administered (Box 53.20).

BOX 53.18 **Grading Scale for Symptoms in Patients With an Anterior or Superior Mediastinal Mass**

Asymptomatic
Mild: Can lie supine with some cough/pressure sensation
Moderate: Can lie supine for short periods but not indefinitely
Severe: Cannot tolerate supine position

BOX 53.19 **Stratification of Patients with Mediastinal Masses Regarding Safety for General Anesthesia**

A.	**Safe**	(I)	Asymptomatic adult, CT minimal tracheal/bronchial diameter >50% of normal
B.	**Unsafe**	(I)	Severely symptomatic adult or child
		(II)	Children with CT tracheal/bronchial diameter <50% of normal, regardless of symptoms
C.	**Uncertain**	(I)	Mild/moderate symptomatic child with CT tracheal/bronchial diameter >50% of normal
		(II)	Mild/moderate symptomatic adult with CT tracheal/bronchial diameter <50% of normal
		(III)	Adult or child unable to give history

CT, Computed tomography scan.

Development of airway or vascular compression requires that the patient be awakened as rapidly as possible and then other options for the procedure be explored. Intraoperative life-threatening airway compression usually responds to one of two therapies: either repositioning of the patient (it must be determined before induction if there is a position that causes less compression and less symptoms) or rigid bronchoscopy and ventilation distal to the obstruction (this means that an experienced bronchoscopist and equipment must always be immediately available in the operating room for these cases). The rigid bronchoscope, even if passed into only one mainstem bronchus, can be used for oxygenation during resuscitation (see "Rigid Bronchoscopy," earlier).[293] Once adequate oxygenation has been restored the rigid bronchoscope can be used to position an airway exchange catheter, over which an ETT is passed after the bronchoscope is withdrawn. An alternative technique to secure the airway with rigid bronchoscopy is to first mount an ETT over a small rigid bronchoscope (e.g., 6 mm) and then perform rigid bronchoscopy using the bronchoscope to deliver the ETT distal to the obstruction.[294]

Institution of femorofemoral ECMO before induction of anesthesia is a possibility for some adult patients who are "unsafe" for NPIC general anesthesia. The concept of CPB "standby" during attempted induction of anesthesia is fraught with danger[295] because there is not enough time after a sudden airway collapse to establish CPB before hypoxic cerebral injury occurs.[296] Other options for "unsafe" patients include local anesthetic biopsy of the mediastinal mass or biopsy of another node (e.g., supraclavicular), preoperative radiotherapy with a nonradiated "window" for subsequent biopsy, preoperative chemotherapy or short-course steroids, and CT-guided biopsy of mass or drainage

BOX 53.20 **Management for All Patients With a Mediastinal Mass and an Uncertain Airway for General Anesthesia**

1. Determine optimal positioning of patient preoperatively
2. Secure airway beyond stenosis when patient is awake, if feasible
3. Have rigid bronchoscope and surgeon available at induction of anesthesia
4. Maintain spontaneous ventilation if possible *(noli pontes ignii consumere)*
5. Monitor for airway compromise postoperatively

of a cyst. The salient points in managing a patient with an anterior or superior mediastinal mass include[297]:

1. In virtually all children and adults with a mediastinal mass, diagnostic procedures and imaging and can be performed, if necessary, without subjecting the patient to the risks of general anesthesia.[298]
2. An extrathoracic source of tissue for diagnostic biopsy (pleural effusion or extrathoracic lymph node) should be sought as an initial measure in every patient.
3. Regardless of the proposed diagnostic or therapeutic procedure, the flat, supine position is never mandatory.
4. In the high-risk child (Box 53.21) without extrathoracic lymphadenopathy or a pleural effusion, prebiopsy steroid therapy is justifiable.[299] In this case, coordination with oncology, surgery, and anesthesiology is essential to organize timing of the biopsy. An alternative to preoperative steroids in the cooperative high-risk patient includes irradiating the tumor while leaving a small area covered with lead for subsequent biopsy.

With improved awareness of the risk of acute intraoperative airway obstruction in these patients, life-threatening events are now less likely to occur in the operating room. In children these events now tend to occur preoperatively if the patient is forced to assume a supine position for imaging. In adults, acute airway obstruction is now more likely to occur postoperatively in the recovery room.[300] Vigilance must be maintained throughout the entire perioperative period.

Thymectomy for Myasthenia Gravis

Myasthenia gravis is a disease of the neuromuscular junction; affected patients have weakness caused by a decreased number of acetylcholine receptors at the motor endplate.[301] Patients may or may not have an associated thymoma. Thymectomy is frequently performed to induce clinical remission, even in the absence of a thymoma. The effects of muscle relaxants are modified by this disease; myasthenic patients are resistant to succinylcholine and extremely sensitive to nondepolarizing blockers. Thymectomy may be performed via full or partial sternotomy, or with a minimally invasive approach via a transcervical incision or VATS. For thymectomy with a thymoma, a sternotomy is used. In the absence of an identifiable tumor, minimally invasive techniques are commonly used. Ideally, the use of neuromuscular relaxation is avoided. Induction of anesthesia with propofol, remifentanil, and topical anesthesia of the airway facilitates intubation without the use of muscle relaxants. Alternatively, inhalational induction with a halogenated agent such as sevoflurane may be performed.[302] For sternotomy, combined general and thoracic epidural anesthesia is a useful technique.

Neuromuscular blockers should be used with caution in myasthenic patients because of the increased sensitivity to nondepolarizing muscle relaxants that might result in prolonged postoperative partial paralysis associated with increased morbidity and the need for postoperative mechanical ventilation.[303] The cyclodextrin derivative, sugammadex, encapsulates steroidal neuromuscular blocking agents. Sugammadex has been approved as a therapy for reversal of neuromuscular blockade induced by the steroidal nondepolarizing neuromuscular blocking drugs, rocuronium and vecuronium. Sugammadex is used to reverse rocuronium in myasthenics.[304] Sugammadex dosing is dictated by the train-of-four response using a neuromuscular blockade monitor.

Most patients take pyridostigmine, an oral anticholinesterase, and many patients are on immunosuppressive medication (e.g., corticosteroids). On the day of surgery, pyridostigmine dosing should ensure that the patient's usual regimen is provided during the immediate perioperative period. A few patients require intravenous dosing with neostigmine until they are able to resume oral intake of pyridostigmine. A scoring system was devised for prediction of the need for prolonged mechanical ventilation after thymectomy via sternotomy.[305] Among the criteria that contributed to the predicted need for support were disease duration longer than 6 years, chronic respiratory illness, pyridostigmine dosage greater than 750 mg/day, and vital capacity less than 2.9 L. The relevance of this score has diminished with better preoperative preparation and minimally invasive surgery.[306] Referral for surgery early in the course of the disease and stabilization of symptoms with corticosteroids, intravenous immunoglobulin and plasmapheresis, combined with the increased use of minimally invasive approaches, have made the need for postoperative ventilation infrequent. In optimized patients, mean hospital length of stay can be reduced to 1 day after minimally invasive, and 3 days after transsternal thymectomy.[307] Patients should remain on their full medical regimen postoperatively. The remission from myasthenia gravis after thymectomy occurs slowly over a period of months to years.

BOX 53.21 Predictors of Airway Compromise in Children With a Mediastinal Mass

1. Anterior location
2. Histological diagnosis of lymphoma
3. Superior vena cava syndrome
4. Radiologic evidence of major vessel compression or displacement
5. Pericardial or pleural effusion

NONINTUBATED THORACIC SURGERY

During the original thoracic surgery procedures in the late 1800s, patients were anesthetized with ether and breathed spontaneously without intubation. During open thoracotomy without oxygen supplementation, this led to progressive hypoxemia and hypercapnia and limited the duration of safe surgery. With improvements in anesthesia and VATS there has been a trend to return to nonintubated thoracic surgery in some centers. Initial reports focused on pleural drainage, lung biopsies, drainage of empyema, and similar procedures.[308] More recently the use of nonintubated surgery has expanded to lobectomy, segmentectomy, and other more complex operations. Benefits may include shorter hospital stays and fewer postoperative complications.[309]

Techniques of nonintubated thoracic anesthesia include a variety of methods of sedation or general anesthesia that maintain spontaneous ventilation.[310] Patients should receive supplemental oxygen to avoid hypoxemia. Patients may develop hypercapnia; however, mild hypercapnia is usually well tolerated. For patients who are hypercapnic at rest, the use of high-flow nasal oxygen may be beneficial. Dexmedetomidine provides satisfactory sedation in combination with epidural anesthesia for VATS in patients with severe respiratory dysfunction. If general anesthesia is selected, with either total intravenous or volatile anesthesia, an LMA is useful for nonintubated procedures. Regional anesthesia is commonly provided by either intercostal, paravertebral, or epidural blocks. Either of two ultrasound-guided chest wall blocks (serratus anterior plane and erector spinae plane [ESP]) (see later) may be appropriate in some patients. A remifentanil infusion may be helpful in patients who are tachypneic without hypoxemia. Also, remifentanil may decrease the cough reflex. But the risk of apnea must be appreciated and ventilation closely monitored. For surgical procedures that involve manipulation near the hilum, coughing may be problematic. Chen and associates describe the use of an intrathoracic vagal block with 2 to 3 mL of 0.25% bupivacaine injected close to the vagus nerve at the level of the lower trachea in the right hemithorax or in the aortopulmonary window on the left. This resulted in abolition of coughing for 3 hours.[311]

EXTRACORPOREAL MEMBRANE OXYGENATION

There is an increasing use of ECMO to manage oxygenation in thoracic surgery. ECMO has a well-established role in lung transplantation. There have been an increasing number of case reports of ECMO being used to manage oxygenation during other types of thoracic surgery where oxygenation cannot be maintained with conventional techniques.[312] The advantage of utilizing ECMO includes the ability to maintain oxygenation and carbon dioxide removal in cases where proper ventilation is not feasible or sufficient because of patient-specific comorbidities or anatomic derangements. There are multiple reports and case series describing the use of ECMO in patients with critical airway obstruction undergoing tracheal mass removal or stenting.[313] Also, ECMO has been used in patients with poor gas exchange when lung collapse was required. In these reports, elective initiation of ECMO (usually venovenous) prior to induction of anesthesia or prior to the start of the procedure led to acceptable outcomes.[314] A list of potential indications for ECMO in thoracic surgery is included in Box 53.22. Venovenous ECMO can be performed via a single double-lumen cannula (right internal jugular) or two cannulae (usually femoral and jugular). Venoarterial ECMO can be performed with peripheral cannulation (femoral) or central cannulation (e.g., right atrium and ascending aorta). It is useful to monitor cerebral oxygen saturation in addition to peripheral saturation when ECMO is used during surgery.

BOX 53.22 **Potential Indications for Extracorporeal Membrane Oxygenation to Improve Oxygenation During Thoracic Surgery**

- Severe airway obstruction
- Emergency loss of airway
- Extended carinal pneumonectomy
- Severe emphysema undergoing lung volume reduction surgery
- Acute respiratory distress syndrome undergoing thoracotomy and decortication
- Tracheoesophageal fistula repair after previous pneumonectomy
- Esophagectomy after previous pneumonectomy
- Segmentectomy after previous contralateral pneumonectomy
- Thoracotomy after previous single lung transplantation
- Thoracotomy with existing contralateral bronchopleural fistula
- Salvage therapy for severe chest trauma

Postoperative Management

ENHANCED RECOVERY AFTER SURGERY

Enhanced recovery after surgery (ERAS) is a combined multispecialty approach to perioperative management that has been adopted by many surgical specialties.[315] The concept is to mitigate the stress response to surgery and enable a faster recovery. ERAS pathways in lung cancer surgery are associated with reduced complications, a shorter length of stay, and cost savings.[316] A recent panel convened by the European Society of Thoracic Surgeons has published guidelines for ERAS in thoracic surgery (Tables 53.12 and 53.13)[317] with suggestions for both surgical and anesthetic management. Their recommendations (strong or weak) are based on the quality of the evidence (high, moderate, low, and very low) and also the balance between desirable and undesirable effects of each intervention.

TABLE 53.12 Surgical Modifiable Factors for Enhanced Recovery

Surgical Factor	Evidence Level	Recommendation Grade
Nutritional supplements if malnourished	Moderate	Strong
Smoking cessation	High	Strong
Pulmonary rehabilitation for borderline lung function or exercise capacity	Low	Strong
Mechanical and pharmacologic VTE prophylaxis	Moderate	Strong
Antibiotic prophylaxis	High	Strong
VATS for early stage lung cancer	High	Strong
Postoperative incentive spirometry	Low	Strong

VATS, Video-assisted thoracoscopic surgery.

EARLY MAJOR COMPLICATIONS

There are multiple potential major complications that can occur in the immediate postoperative period following thoracic surgery, such as torsion of a remaining lobe after lobectomy, dehiscence of a bronchial stump, or hemorrhage from

TABLE 53.13 Anesthetic Modifiable Factors for Enhanced Recovery

Anesthetic Factor	Evidence Level	Recommendation Grade
Double-lumen tube or bronchial blocker for lung isolation	Moderate	Strong
Lung protective ventilation	Moderate	Strong
Temperature monitoring and active warming	High	Strong
Combined regional and general anesthesia	Low	Strong
Multimodal management of postoperative nausea and vomiting	Moderate	Strong
Inclusion of acetaminophen and nonsteroidal antiinflammatory drugs in analgesia	High	Strong
Euvolemic fluid management	High	Strong
Nonintubated thoracic surgery	Low	Not Recommended

Based on Batchelor T, Rasburn N, Abdelnour-Berchtold E, et al. *Eur J Cardio-Thorac Surg*. 2018, in press.

a major vessel. Fortunately, these are infrequent and when they do occur, the principles of management are as outlined earlier for common and specific procedures. Among the possible complications, two will be discussed in more detail: (1) respiratory failure, because it is the most common cause of major morbidity after thoracic surgery; and (2) cardiac herniation because, although it is rare, it is usually fatal if it is not quickly diagnosed and appropriately treated.

Respiratory Failure

Respiratory failure is a leading cause of postoperative morbidity and mortality in patients undergoing major lung resection. Acute respiratory failure after lung resection is defined as the acute onset of hypoxemia ($PaO_2 < 60$ mm Hg) or hypercapnia ($PaCO_2 > 45$ mm Hg) or the use of postoperative mechanical ventilation for more than 24 hours or reintubation for controlled ventilation after extubation. The incidence of respiratory failure after lung resection is between 2% and 18%. Patients with decreased respiratory function preoperatively are at increased risk of postoperative respiratory complications. In addition, age, the presence of coronary artery disease, and the extent of lung resection play major roles in predicting postoperative mortality and morbidity. Crossover contamination, because of the failure of lung isolation intraoperatively during lung resection in patients with contaminated secretions, can result in contralateral pneumonia and postoperative respiratory failure.[318] Mechanical ventilation during the postoperative period after lung resection is associated with the risk of acquired nosocomial pneumonia and bronchopleural fistula.

Decreased pulmonary complications in high-risk patients are associated with the use of thoracic epidural analgesia during the perioperative period.[2] The prevention of atelectasis and secondary infections have been attributed to better preservation of the functional RV, efficient mucociliary clearance, and alleviation of the inhibiting reflexes acting on the diaphragm in patients receiving epidural analgesia.[319] Chest physiotherapy, incentive spirometry, and early ambulation are crucial in order to minimize pulmonary complications after lung resection. For an uncomplicated lung resection, early extubation is desirable to avoid potential complications that can arise as a result of prolonged intubation and mechanical ventilation. Current therapy to treat acute respiratory failure is supportive therapy attempting to provide better oxygenation, treat infection, and provide vital organ support without further damaging the lungs.

Cardiac Herniation

Acute cardiac herniation is an infrequent but well-described complication of pneumonectomy, where the pericardium is incompletely closed or the closure breaks down.[320] It usually occurs immediately or within 24 hours after chest surgery and is associated with greater than 50% mortality. Cardiac herniation may also occur after a lobar resection with pericardial opening, or in other chest tumor resections involving the pericardium or in trauma.[321] When cardiac herniation occurs after a right pneumonectomy, the clinical presentation is caused by impairment of the venous return to the heart with a concomitant increase in CVP, tachycardia, profound hypotension, and shock. An acute superior vena cava syndrome ensues because of the torsion of the heart.[322] In contrast, when the cardiac herniation occurs after a left-sided pneumonectomy, there is less cardiac rotation, but the edge of the pericardium compresses the myocardium. This may lead to myocardial ischemia, the development of arrhythmias, and ventricular outflow tract obstruction. Cardiac herniation occurs after chest closure because of the pressure difference between the two hemithoraces. This pressure difference may result in the heart being extruded through a pericardial defect.

Management for a patient with a cardiac herniation should be considered as dire emergent surgery. The differential diagnosis should include massive intrathoracic hemorrhage, pulmonary embolism, or mediastinal shift from improper chest drain management. Early diagnosis and immediate surgical treatment by relocation of the heart to its anatomic position with repair of the pericardial defect or by the use of analogous or prosthetic patch material is key to patient survival. Because these patients have undergone a previous thoracotomy, all precautions should be taken for a "redo" exploration. This includes the use of large-bore intravenous catheters and an arterial line. Maneuvers to minimize the cardiovascular effects include positioning the patient in the full lateral position with the operated side up. Because time is crucial an SLT is used. Vasopressors or inotropes, or both, are required to support the circulation while exploration takes place. The use of TEE intraoperatively and after resuscitation and relocation of the heart can be considered during pericardial patch repair to prevent excessive compression of the heart by the repair.[323] In general, patients undergoing an emergency thoracic reexploration remain intubated and are transferred to the intensive care unit postoperatively.

Postoperative Analgesia

Studies prior to 1990 consistently reported a 15% to 20% rate of major respiratory complications (atelectasis, pneumonia, respiratory failure) within the first 3 days

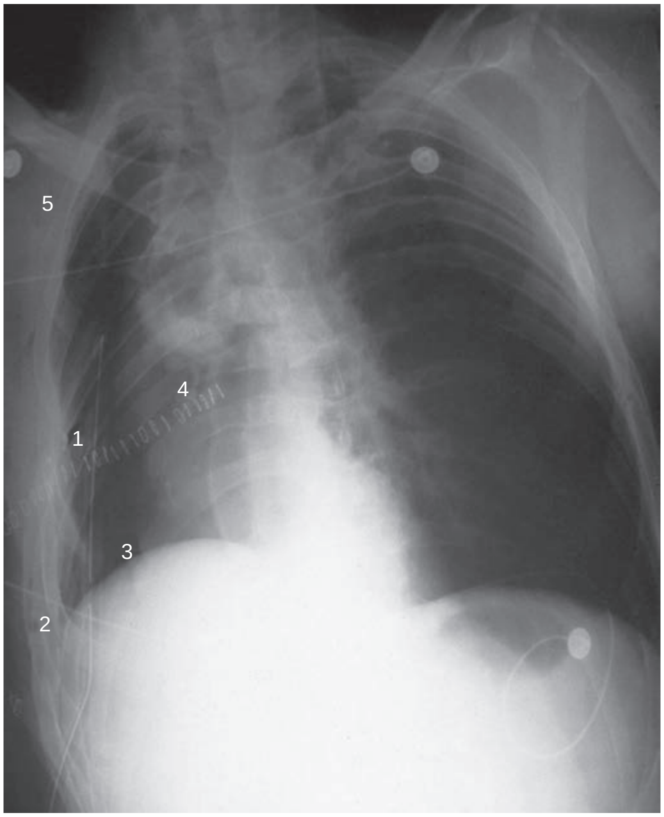

Fig. 53.56 Multiple sources of afferent transmission of pain sensations after thoracotomy. (1) Intercostal nerves at the site of the incision (usually T4-T6); (2) intercostal nerves at the site of chest drains (usually T7-T8); (3) phrenic nerve afferents from the dome of the diaphragm; (4) vagal nerve innervation of the mediastinal pleura; (5) brachial plexus.

after thoracic surgery.[1] This time of onset may relate to the unique pattern of recovery of pulmonary function following thoracotomy, which shows a delay in the initial 72-hour postoperative period that is not seen with other major surgical incisions.[324] The incidence of postthoracotomy respiratory complications has shown an overall decline to less than 10%, whereas the cardiac complication rate has not changed.[2] Improvements in postoperative care, specifically pain management, are the major cause of this decline.

There are multiple sensory afferents that transmit nociceptive stimuli following thoracotomy (Fig. 53.56). These include the incision (intercostal nerves T4-T6), chest drains (intercostal nerves T7-T8), mediastinal pleura (vagus nerve, CN 10), central diaphragmatic pleura (phrenic nerve, C3-C5),[325] and ipsilateral shoulder (brachial plexus). There is no one analgesic technique that can block all these various pain afferents, so analgesia should be multimodal. The optimal choice for an individual patient depends on patient factors (i.e., contraindications, preferences), surgical factors (i.e., type of incision), and system factors (i.e., available equipment, monitoring, nursing support). The ideal postthoracotomy analgesic technique will include three classes of drugs: opioids, antiinflammatory agents, and local anesthetics.

SYSTEMIC ANALGESIA

Opioids

Systemic opioids alone are effective in controlling background pain, but the acute pain component associated with cough or movement requires plasma levels that produce sedation and hypoventilation in most patients. Even when administered by patient-controlled devices, pain control is generally poor[326] and patients have interrupted sleep patterns when serum opioid levels fall below the therapeutic range.

Nonsteroidal Antiinflammatory Drugs

NSAIDs can reduce opioid consumption more than 30% following thoracotomy and are particularly useful treating the ipsilateral shoulder pain that is often present postoperatively and is poorly controlled with epidural analgesia. NSAIDs act through reversible inhibition of COX, which has antiinflammatory and analgesic effects but can also be associated with decreased platelet function, gastric erosions, increased bronchial reactivity, and decreased renal function. Acetaminophen is an antipyretic/analgesic with weak COX inhibition and can be administered orally or rectally in doses up to 4 g/day. It is effective against shoulder pain and has a low toxicity compared with more potent COX-inhibiting NSAIDs.[327]

Ketamine

Ketamine is used increasingly for postthoracotomy pain as part of multimodal analgesic therapy in combination with regional analgesia, opioids, and antiinflammatory agents.[328] Ketamine can be started intraoperatively as low-dose boluses or infusions and continued postoperatively as an infusion. Common postoperative infusion doses are in the range of 0.1 to 0.15 mg/kg/h.[329] The possibility of psychomimetic effects with ketamine is always a concern but is rarely seen with analgesic, subanesthetic doses. Although perioperative ketamine is useful to reduce acute postthoracotomy pain, it is unclear if it has any benefit in reducing chronic postthoracotomy pain.[330]

Dexmedetomidine

Dexmedetomidine, a selective adrenergic alpha-2 receptor agonist, has been reported as a useful adjunct for postthoracotomy analgesia and can significantly decrease the requirement for opioids when used in combination with other analgesics.[331] Maintenance infusion doses for analgesia in children and adults are in the range of 0.3 to 0.4 μg/kg/h.[332] It is associated with some hypotension, but it seems to preserve renal function.

Intravenous Lidocaine

Intra- and postoperative lidocaine infusions are frequently included in multimodal analgesic regimens for a wide variety of surgical procedures.[333] Commonly used doses range between 1 to 2 mg/kg/h. Intravenous lidocaine has not been well studied for postthoracotomy/VATS pain. Small studies of intravenous lidocaine in thoracic surgery have had mixed results.[334,335]

Gabapentinoids

Gabapentin and pregabalin are well known drugs used to treat chronic pain syndromes. Their usefulness in treating acute pain following thoracic surgery is unclear. A single dose of preoperative gabapentin did not show any benefit when used in conjunction with epidural analgesia.[336] One study of postthoracotomy pain using intravenous morphine analgesia showed a benefit when gabapentin was administered pre- and postoperatively.[337]

LOCAL ANESTHETICS/NERVE BLOCKS

Intercostal Nerve Blocks

Regional blocks of the intercostal nerves supplying the dermatomes of the surgical incision can be an effective adjunct to methods of postthoracotomy analgesia. These can be done percutaneously or under direct vision when the chest is open. The duration of analgesia is limited to the duration of action of the local anesthetic used, and the blocks will need to be repeated to have any useful effect on postoperative lung function. Indwelling intercostal catheters are an option but they can be difficult to position reliably percutaneously. Nerve blocks are useful supplements for the pain associated with the multiple small-port incisions and chest drains after VATS. It is important to avoid injection into the intercostal vessels, which are adjacent to the nerve in the intercostal groove. It is also important to place the block near the posterior axillary line to be certain to block the lateral cutaneous branch of the intercostal nerve. Total bupivacaine dose for a single session of blocks should not exceed 1 mg/kg (e.g., for a 75-kg patient: 3 mL bupivacaine 0.5% with epinephrine 1:200,000 at each of 5 levels).

Liposomal encapsulated bupivacaine has a slow release of local anesthetic over a period of 72 to 96 hours. Liposomal bupivacaine was originally introduced for local wound infiltration; however, it has been also used for intercostal blocks for thoracotomy and VATS. In combination with multimodal techniques, the postoperative analgesia may be comparable to thoracic epidural analgesia.[338] The onset of useful analgesia with liposomal bupivacaine is at least 45 minutes, which may be a problem if it is injected only at the end of surgery.[339]

Epidural Analgesia

The routine use of neuraxial analgesia for postthoracotomy patients is a well-established concept. Spinal injection of opioids can have a duration of analgesia that approaches 24 hours after thoracotomy. Because of the concerns of possible infection with subarachnoid catheters and the need to repeat spinal injections, investigation and therapy has focused on epidural techniques. A meta-analysis of respiratory complications after various types of surgery has shown that epidural techniques reduce the incidence of respiratory complications.[340] Thoracic epidural analgesia for thoracic surgery with infusions of local anesthetic and opioids has become the “gold-standard” against which other techniques of postthoracotomy analgesia are measured. Opioid and local anesthetic combinations provide better analgesia at lower doses than either drug alone.[341] The use of epidural infusions has an excellent record for patient safety when used on routine postoperative surgical wards.[342] The use of a paramedian approach to the epidural space in the midthoracic levels (Fig. 53.57) has improved the success rate for many clinicians. Ultrasound guidance has not yet proven to be as useful for thoracic epidural catheter placement as it has for other types of regional blockade.[343] Identification of the epidural space is most commonly performed with a loss-of-resistance technique that is operator dependent. After injection of a small volume of saline (5 mL) through the Tuohy needle, the epidural pressure can be transduced and a typical waveform can be seen that identifies the epidural space with a high degree of sensitivity and specificity.[344]

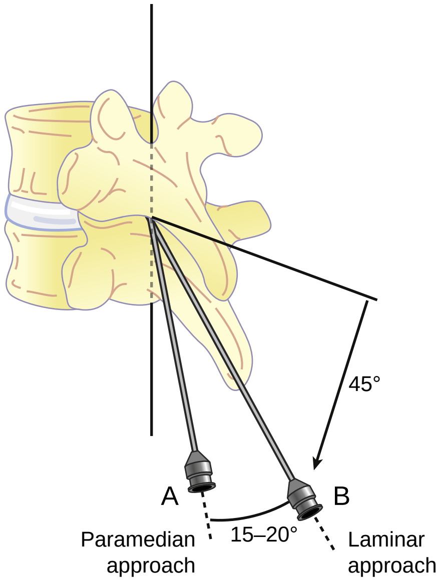

Fig. 53.57 (A) The paramedian approach to the epidural space is now favored by most anesthesiologists at the midthoracic levels. The needle is inserted 1 cm lateral to the superior tip of the spinous process and then advanced perpendicular to all planes to contact the lamina of the vertebral body immediately below. The needle is then “walked” up the lamina at an angle rostrally (45 degrees) and medially (20 degrees) until the rostral edge of the lamina is felt. The needle is then advanced over the edge of the lamina seeking a loss of resistance on entering the epidural space after transversing the ligamentum flavum. (B) The laminar approach is favored by some practitioners. The needle is inserted next to the rostral edge of the spinous process and advanced straight without any angle from the midline. (Reprinted with permission from Ramamurthy S. Thoracic epidural nerve block. In: Waldman SD, Winnie AP, eds. *Interventional Pain Management*. Philadelphia: Saunders; 1996)

Research has shed light on the pharmacology, which underlies the synergy between local anesthetics and opioids to produce segmental epidural analgesia. In a double-blind randomized study, Hansdottir and associates[345] compared epidural infusions of lumbar sufentanil, thoracic sufentanil, and thoracic sufentanil plus bupivacaine (S+B) for postthoracotomy analgesia. Infusions were titrated for equianalgesia at rest. Thoracic sufentanil plus bupivacaine provided significantly better analgesia with movement and less sedation than the other infusions. Although sufentanil dosages and serum levels were significantly lower in the combined (S+B) group than in the other two groups, lumbar cerebral spinal fluid levels of sufentanil at 24 and 48 hours were higher in the combined group than in the thoracic sufentanil group (this suggests that the local anesthetic facilitates entry of the opioid from the epidural space into the cerebral spinal fluid).

In patients with severe emphysema, analgesic doses of thoracic epidural analgesia plus bupivacaine do not cause any significant reduction in lung mechanics or increase in airway resistance.[346] In volunteers, a thoracic level of epidural blockade increases FRC.[347] This increase is largely because of an increase in thoracic gas volume caused by a fall in the resting level of the diaphragm without a fall in tidal volume. Differences in lipid solubility that create relatively minor clinical differences in the effects of opioids when used systemically cause major differences in the effects of these same opioids when used neuraxially. The highly lipid-soluble agents (e.g., fentanyl, sufentanil) are associated with narrow dermatomal spread, rapid onset, and low incidence of pruritus/nausea, and can be potentiated by epinephrine. However, these lipid-soluble agents have significant absorption and systemic effects when used as epidural infusions.[348] For incisions that cover many dermatomes (e.g., sternotomy) or for procedures that have combined abdominal and thoracic incisions (e.g., esophagectomy), the hydrophilic opioids (e.g., morphine, hydromorphone) are preferable.

Paravertebral Block

The paravertebral space is a potential space deep to the endothoracic fascia that the intercostal nerve traverses as it passes from the intervertebral foramen en route to the intercostal space (Fig. 53.58). A catheter can be placed in the thoracic paravertebral space either percutaneously or by approaching the space anteriorly and directly when the chest is open intraoperatively.

There is also a combined percutaneous/direct-vision method in which the tip of the Tuohy needle is advanced percutaneously into the paravertebral space under direct vision either during open thoracotomy or VATS. The tip of the needle is seen to enter the paravertebral space and the pleura is not punctured. Saline is injected via the Tuohy needle to hydrodissect the paravertebral space and an epidural catheter is passed into the pocket that has been created in the paravertebral space and then secured at the skin.

Paravertebral local anesthetics provide a reliable multilevel intercostal blockade that tends to be unilateral with a low tendency to spread to the epidural space. Clinically the analgesia is comparable to that from epidural local anesthetics.[349] Studies comparing paravertebral versus thoracic epidural analgesia for thoracotomies have suggested the following advantages for paravertebral blockade[350]: comparable analgesia; fewer failed blocks; decreased risk of neuraxial hematoma; and less hypotension, nausea, or urinary retention. Because there is the option to place the paravertebral catheter under direct vision, this may contribute to the lower incidence of failed blocks versus thoracic epidural analgesia.

Paravertebral infusions in combination with NSAIDs and systemic opioids are a reasonable alternative to epidural techniques in children or some patients with contraindications to neuraxial blockade. Using common therapeutic doses (e.g., 0.1 mL/kg/h of bupivacaine 0.5%), serum bupivacaine levels can approach toxic levels by 4 days.[351] An alternative regime for paravertebral infusions is lidocaine 1% (1 mL/10 kg/h; maximum 7 mL/h). It has not yet been demonstrated if paravertebral analgesia can contribute to a decrease in respiratory morbidity in high-risk cases, which has been shown for thoracic epidural analgesia.[352]

Ultrasound-Guided Blocks

The increasing use of ultrasound in regional anesthesia has improved the success of percutaneous paravertebral blocks[353] and has enabled the development of several useful new blocks for postthoracotomy/VATS analgesia.

The serratus anterior plane block is performed at the level of the fifth rib in the midaxillary line. At this level, the serratus anterior muscle can be identified overlying the ribs, with the latissimus dorsi muscle lying superior to the serratus muscle. Needle insertion can be performed in-plane or out-of-plane, depending on provider preference. The serratus anterior plane block can be achieved by injecting local anesthetic either above or below the serratus muscle, with equivalent analgesic spread with both techniques. Serratus anterior plane block has been shown to improve the analgesia provided by patient-controlled morphine.[354]

The ESP block is an ultrasound-guided block for both acute and chronic postthoracotomy pain. It may, in fact, be a variant of the paravertebral block. Injection of 20 mL of solution into the fascial plane deep into the erector spinae

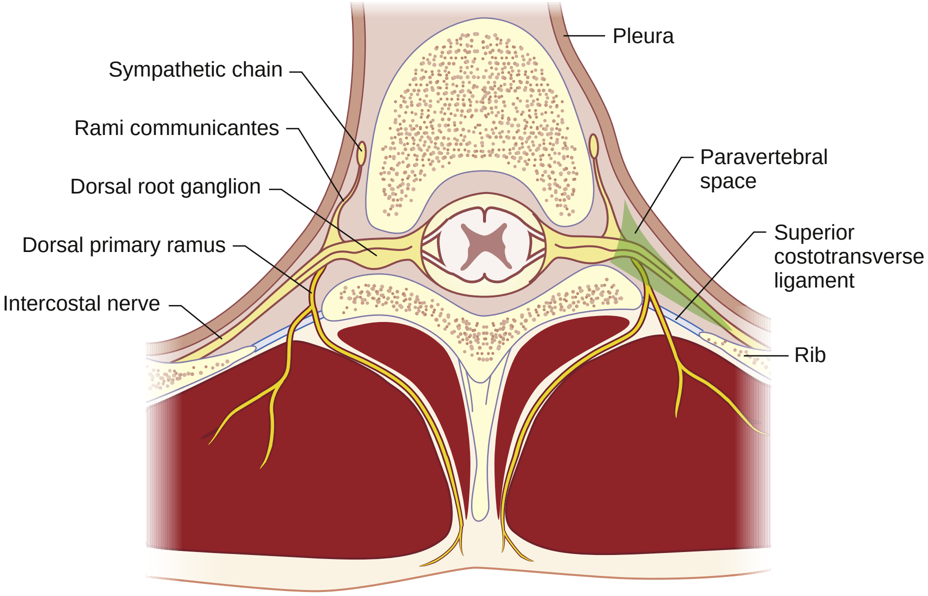

Fig. 53.58 Diagram of the paravertebral space. The space is bound medially by the vertebral body, posteriorly by the costotransverse ligaments and the heads of the ribs, and anteriorly by the endothoracic fascia and parietal pleura. (From Conacher ID, Slinger PD. *Thoracic Anesthesia.* 3rd ed. Kaplan J, Slinger P, eds. Philadelphia: Churchill Livingstone; 2003.)

muscle at the level of the T5 transverse process can result in a spread of injectate from C7 to T8 vertebral levels.[355] This block has been described for postthoracotomy analgesia rescue in a case of failed epidural analgesia in a patient receiving prophylactic anticoagulation.[356] The benefit of an ESP block over a paravertebral block may be the more obvious end-point for an ESP block as the needle tip contacts the transverse process of the vertebra. An ultrasound-visible regional anesthetic needle (e.g., 8 cm, 17-gauge) is inserted to contact the transverse process of the appropriate thoracic vertebra deep to the anterior fascia of the erector spinae muscle (Fig. 53.59). A total of 20 to 25 mL of local anesthetic solution (e.g., 0.2% ropivacaine) is administered in 5 mL aliquots under direct vision. A catheter is then passed 5 cm distal to the tip of the needle and an infusion of 5 to 8 mL/h is begun.

POSTOPERATIVE PAIN MANAGEMENT PROBLEMS

Shoulder Pain

Ipsilateral shoulder pain is very common after thoracic surgery. It has been documented in 78% of patients immediately postoperatively.[357] In 42% of patients this pain was judged to be clinically relevant. By postoperative day 4, 32% of patients had shoulder pain, but only 7% had clinically relevant shoulder pain. Shoulder pain occurred after both open and VATS surgery; the incidence may be decreased after VATS. This pain was felt to be of two major types:

1. Referred pain (55%). This is thought to originate from phrenic nerve afferent fibers and related to diaphragmatic or mediastinal irritation.
2. Musculoskeletal (45%). This pain was associated with tenderness of the involved shoulder muscles and pain with movement.

Of the two types, the musculoskeletal pain was more intense and more difficult to treat.

Shoulder pain is not treated by any of the common regional blocks performed for thoracic surgery (e.g., thoracic epidural analgesia, paravertebral block). Shoulder pain is most responsive to antiinflammatories. Phrenic nerve infiltration and interscalene brachial plexus block[358] have had some success but carry a risk of causing diaphragm dysfunction.

Postthoracotomy Neuralgia and Chronic Incisional Pain

In one prospective study, chronic postoperative pain at 6 months was documented in 33% of patients after thoracotomy and 25% after VATS.[359] In this study, chronic pain was not associated with preoperative psychosocial measurements found to correlate with chronic postoperative pain in other types of surgery. Chronic pain was associated with acute postoperative pain. This suggests that chronic pain after thoracic surgery may be partially preventable by intensive management of acute postoperative pain.[360]

MANAGEMENT OF OPIOID TOLERANT PATIENTS

The opioid tolerant patient requiring thoracic surgery presents a significant challenge. Patients may be using physician prescribed opioids for pain related to their thoracic pathology, or other chronic pain syndromes. Active abusers of narcotics or those in a rehabilitation program receiving daily methadone also are included in this group. Whenever possible, patients should take their regular analgesia or methadone preoperatively; otherwise substitute opioids must be provided. The opioid doses required to produce adequate postoperative analgesia are increased.

A multimodal analgesic regimen is optimal. A choice must be made regarding the method of increased opioid delivery, either systemically and/or through an epidural. An increased narcotic dose may be provided in the epidural solution, or standard narcotic concentrations may be used in the epidural with additional systemic narcotic. de Leon-Casasola and Yarussi[361] report that higher epidural doses of opioid can curtail the appearance of narcotic withdrawal in most patients. More frequently, the patient receives a standard or slightly increased concentration of opioid in the epidural infusion and additional systemic opioid to minimize the occurrence of withdrawal. A convenient way to provide drug delivery in patients not immediately able to take oral medication is in the form of a transdermal fentanyl patch. Systemic opioids can be provided as a continuous intravenous infusion or in oral format.

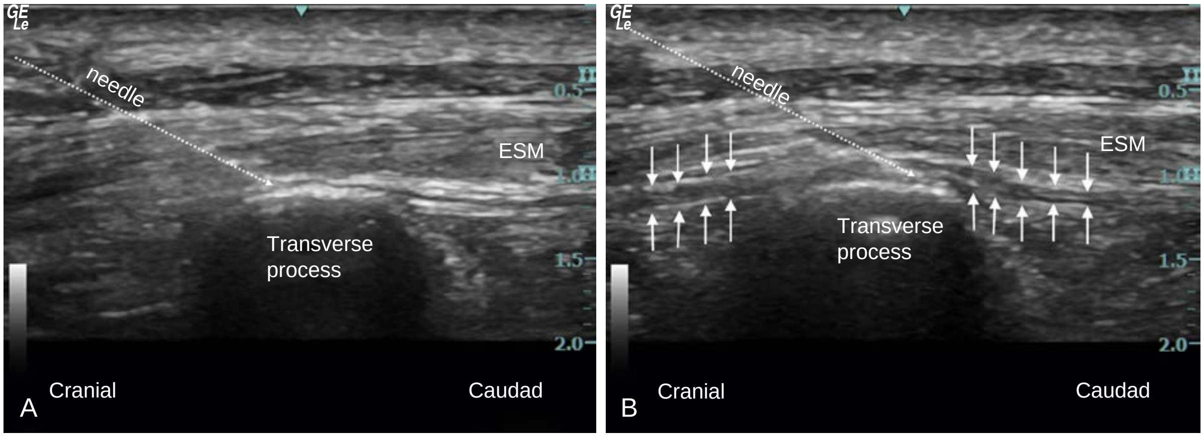

Fig. 53.59 (A) The erector spinae plane block. The ultrasound probe is placed lateral to the spinous process to obtain a parasagittal view of the tip of the targeted transverse process with overlying erector spinae muscle *(ESM)*. The block needle *(dotted arrow)* is advanced in a cranial-caudal direction to contact the transverse process. (B) Correct needle tip position is signaled by linear spread of local anesthetic *(solid arrows)* deep to the ESM and superficial to the transverse process. (Photos courtesy KJ Chin Medicine Professional Corporation.)

Patient-controlled analgesic techniques are often difficult to manage in these patients and they may be best managed with fixed dosage regimens that are modified as needed. Ultimately, after dose titration the patient may be receiving both increased epidural opioid and greater than preoperative doses of systemic opioid, without significant side effects. Patients in whom epidural bupivacaine-morphine analgesia is inadequate may respond to a switch to bupivacaine-sufentanil.[362] Patients in drug rehabilitation programs with methadone may be reluctant to modify their methadone dose perioperatively, having struggled to establish a stable dose in the past. They frequently can take their full methadone dose throughout the perioperative period.

Supplemental therapies to be considered for these patients include adding epinephrine 5 µg/mL to the epidural infusion solution and the addition of low-dose continuous intravenous ketamine infusions.[363] All opioid-tolerant patients require frequent adjustment of analgesic doses. Despite this, pain scores of 4 to 5 out of 10 with movement are often the lowest achievable. The increased analgesic requirements for opioid-tolerant patients are for a longer duration postoperatively than the usual need for analgesia in opioid-naïve patients.

Anesthesia for Cardiac Surgical Procedures

MUHAMMAD F. SARWAR, BRUCE E. SEARLES, MARC E. STONE, and LINDA SHORE-LESSERSON

KEY POINTS

- Common cardiac surgical procedures in adults include coronary revascularization with either cardiopulmonary bypass (CPB) or off pump, as well as cardiac valve repair or replacement for valvular regurgitation or stenosis, surgical management of heart failure (e.g., ventricular assist devices, extracorporeal membrane oxygenation, cardiac transplantation), initial repair of or reoperation for congenital heart disease, surgical ablation of atrial fibrillation, pericardiocentesis or pericardiectomy, and repair of traumatic injuries to the heart or thoracic aorta.
- Patients undergoing "redo" cardiac surgery (i.e., those who have previously had a median sternotomy) warrant special concern about the possibility of sudden, massive hemorrhage. At least 2 units of blood should be immediately available for all such cases.
- The choice of anesthetic drugs and techniques for inducing anesthesia should include consideration of the patient's cardiac pathophysiology and other comorbid conditions. Hypotension may result from vasodilation secondary to decreased sympathetic tone induced by anesthetics, particularly in patients with poor left ventricular function. Conversely, hypertension may occur from preinduction anxiety or sympathetic stimulation caused by laryngoscopy and endotracheal intubation.
- During the prebypass period, hemodynamic and metabolic stability of the patient should be achieved while making preparations for CPB. The degree of surgical stimulation varies markedly during this period.
- CPB activates the extrinsic and intrinsic coagulation pathways and alters platelet function through the influence of hemodilution, hypothermia, and contact activation by bypass circuit materials.
- Problems that may occur during the postbypass or postoperative time periods include hypotension resulting from surgical or technical failure, left or right ventricular dysfunction, vasoplegia syndrome, or left ventricular outflow tract obstruction. Other potential problems include dysrhythmias, pulmonary complications (e.g., atelectasis, bronchospasm, mucus or blood plugging of the endotracheal tube, pulmonary edema, hemothorax, pneumothorax), metabolic disturbances (e.g., hypokalemia, hyperkalemia, hypocalcemia, hypomagnesemia, hyperglycemia), and bleeding and coagulopathy.
- The Society of Thoracic Surgeons (STS), the Society of Cardiovascular Anesthesiologists, and the American Society of ExtraCorporeal Technology published a joint statement on practice guidelines for transfusion and blood conservation in cardiac surgery. A European Guideline published by the European Association for Cardio-Thoracic Surgery and European Association of Cardiothoracic Anesthesiology confirm these recommendations. The guidelines include recommendations regarding the following: (1) use of drugs that decrease postoperative bleeding, including antifibrinolytic drugs; (2) techniques for conserving blood and minimizing hemodilution, including cell saver sequestration, retrograde priming of the pump, and normovolemic hemodilution; and (3) implementation of transfusion algorithms supported with point-of-care testing.
- The incidence of overt postoperative stroke after isolated coronary artery bypass grafting (CABG) surgery has decreased significantly to 1.2% despite the more frequent and current prevalence of diabetes mellitus and hypertension. The major risk factor for central nervous system injury or dysfunction is particulate and microgaseous emboli; other factors include cerebral hypoperfusion and the inflammatory response to surgery and CPB.
- STS guidelines state that blood glucose levels should be maintained at less than 180 mg/dL throughout the perioperative period, although many centers treat cardiac surgical patients somewhat more aggressively with continuous insulin infusions in an attempt to keep glucose levels lower than 150 mg/dL. Hypoglycemia should be avoided.

KEY POINTS—cont'd

- Postoperative pain after median sternotomy or thoracotomy causes enhanced sympathetic tone and may lead to myocardial ischemia secondary to increased heart rate, pulmonary vascular resistance, myocardial work, and myocardial oxygen consumption. Furthermore, pain may cause "splinting" that interferes with the patient's ability to cough and clear secretions and leads to postoperative respiratory insufficiency.
- Common procedures performed in "hybrid" operating rooms or cardiac interventional suites include electrophysiology procedures and procedures that involve percutaneous management of structural heart lesions. These include valvular lesions and atrial or ventricular septal defects. Other percutaneous procedures performed in non-OR locations include placement of ventricular assist devices, extracorporeal membrane oxygenation, and aortic endovascular stenting.

Cardiovascular Disease in the 21st Century

AGE, GENDER, AND RACE

An estimated 82,600,000 U.S. adults (<1 in 3) have one or more types of cardiovascular disease (CVD), of whom approximately half are 60 years old or older.[1] The prevalence of CVD will likely increase because of the "graying" of the United States (i.e., the aging of our population) and the increasing incidences of obesity and hypertension.[2] Although mortality from coronary artery disease (CAD) specifically has decreased since the 1970s, CVD remains the leading cause of death for both men and women in the United States (Fig. 54.1). Furthermore, approximately 7,588,000 inpatient cardiovascular operations and procedures are performed yearly in the United States, with direct and indirect costs totaling approximately $315.4 billion.[3] As the current healthcare reforms expand treatment coverage, these costs will probably increase.[2]

Despite the common perception that CVD affects mainly men, this is true only in younger age groups. The sex distribution of CVD changes with age; CVD becomes equally prevalent between the sexes by the age of 60 years, and by the age of 80 years, more women than men are affected.[1] The impact of CVD on the health status of U.S. women has gained recognition and is the focus of public education efforts such as the "Go Red for Women" campaign sponsored by the American Heart Association (AHA) and the "Red Dress" project sponsored by the Department of Health and Human Services, the National Institutes of Health, and the National Heart, Lung, and Blood Institute.[4] Furthermore, a series of editorials and articles in the *Journal of Thoracic and Cardiovascular Surgery*[5] and gender-specific practice guidelines for coronary artery surgery in the *Annals of Thoracic Surgery*[6] have emphasized sex differences that affect patients who undergo cardiac surgical procedures. For example, using internal mammary artery (IMA) grafts significantly reduces mortality in patients of both sexes, but, until more recently, these grafts were underused in women.[6] Although some studies have shown that women's short-term survival is worse than men's after coronary artery bypass grafting (CABG) surgery,[7] others have found that 5-year post-CABG survival is actually better in women than in men.[8]

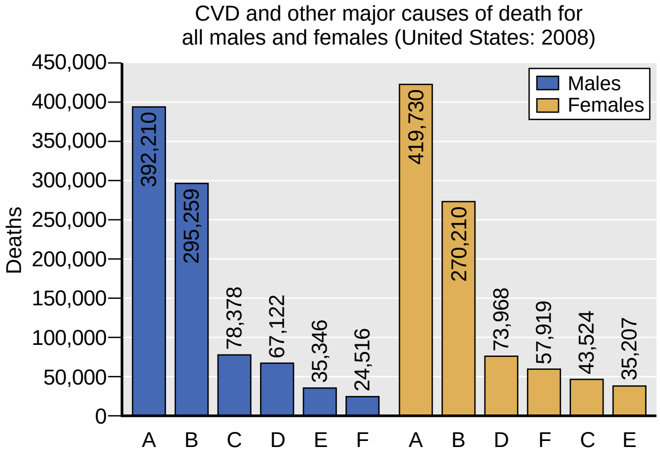

Fig. 54.1 Cardiovascular disease *(CVD)* and other major causes of death for all male and female members of the U.S. population in 2008. (From Roger VL, Go AS, Lloyd-Jones DM, et al. Heart disease and stroke statistics—2012 update: a report from the American Heart Association. *Circulation*. 2012;125:e2–e220; Chart 3–10.)

Mortality resulting from CVD has been consistently more frequent in black than white patients.[1] In 2008, the overall CVD-related death rate per 100,000 persons was 390.4 for black male patients, 287.2 for white male patients, 277.4 for black female patients, and 200.5 for white female patients. Furthermore, racial disparities have been reported in outcomes after CABG: both unadjusted mortality rates and mortality rates adjusted for patient-related characteristics are higher in black patients than in white patients.[9] In fact, as an unfortunate consequence of the public release of quality information through CABG "report cards" in certain states, institutions and individual surgeons may use "racial profiling" in selecting patients for CABG.[10] For example, in New York State, physicians' avoidance of racial and ethnic minorities, who may be at a higher risk for poor outcomes, may have temporarily widened the disparity in CABG use among white versus black and Hispanic patients.

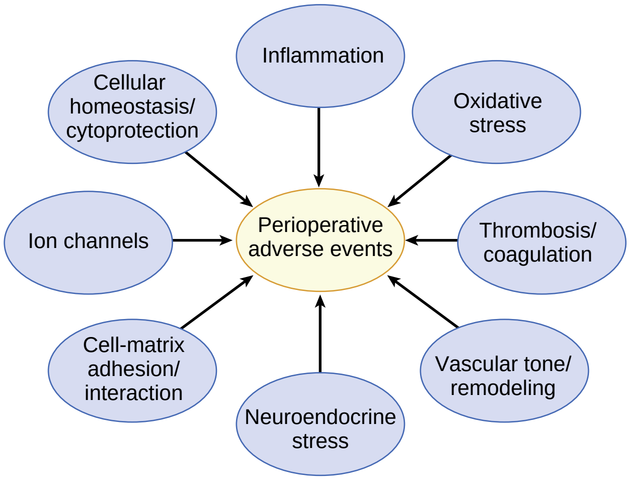
GENETIC INFLUENCES IN CARDIAC DISEASE

Evolving rapidly beyond racial considerations (which are increasingly losing their medical and scientific meaning in the "melting pot" of the United States), *perioperative genomics* is the study of the unique biologic makeup of surgical patients. This field holds promise for uncovering the biologic reasons that patients with similar risk factors can have dramatically different perioperative clinical outcomes.[11] Patients with complex comorbid conditions are exposed to controlled trauma in the cardiac surgical operating room (Fig. 54.2). The hope is that preoperative risk assessment and outcome prediction will soon include testing for genetic markers related to individual differences in inflammatory, thrombotic, and vascular responses to stress related to cardiopulmonary bypass (CPB) and to the operation itself.

One example is the prevention of perioperative myocardial infarction (MI). Mechanisms in the pathogenesis of myonecrosis include the complex acute inflammatory response to surgery and CPB. Functional genetic variants in cytokine and leukocyte-endothelial interaction pathways are independently associated with the severity of myonecrosis after cardiac surgery.[12] Increased concentrations of the most extensively studied inflammatory marker, C-reactive protein (CRP), are associated with increased mortality in patients who undergo CABG.[13] Both increased baseline plasma CRP levels and increased acute-phase postoperative plasma CRP levels are genetically determined.[14] Another pathophysiologic process in perioperative MI is coagulation variability with a tendency toward thrombosis. Polymorphisms in platelet activation[15] and thrombin formation have been associated with myocardial injury and with mortality after cardiac surgery.

Genetic factors have been associated with other postoperative complications. Common genetic variants of CRP and interleukin-6 (IL-6) are significantly associated with the risk of stroke[16] and cognitive decline after cardiac surgery.[17] Angiotensin-converting enzyme (ACE) gene polymorphisms predict a patient's risk of respiratory complications that necessitate prolonged mechanical ventilation after cardiac surgery.[18]

Research in the field of genetic and molecular determinants of outcomes in patients undergoing cardiac surgery continues. In addition to preoperative risk assessments, intraoperative diagnoses and therefore planning for the postoperative care of the patient will be influenced as new discoveries are made.



Inflammation
Cellular homeostasis/ cytoprotection
Oxidative stress
Ion channels
Perioperative adverse events
Thrombosis/ coagulation
Cell-matrix adhesion/ interaction
Vascular tone/ remodeling
Neuroendocrine stress

Fig. 54.2 **Biologic systems and mechanistic pathways genetically associated with perioperative adverse events.** (Redrawn from Podgoreanu MV, Schwinn DA. New paradigms in cardiovascular medicine: emerging technologies and practices: perioperative genomics. *J Am Coll Cardiol.* 2005;46:1965–1977.)

Approach to Anesthesia for the Adult Cardiac Patient

PREOPERATIVE EVALUATION, PREPARATION, AND MONITORING

Heart and Vascular System

Electrocardiography. Standard monitoring of cardiac surgical patients by electrocardiography (ECG) involves using the five-lead electrode system. An electrode is placed on each extremity, and one precordial electrode is placed in the V_5 position (on the left anterior axillary line at the fifth intercostal space). Ischemia detection is greatest (75%) with the V_5 lead. This sensitivity increases to 80% when lead II is paired with a V_5 lead.[19] The addition of a second precordial lead, V_4, increases the sensitivity, thus making it possible to detect nearly 100% of ischemic episodes.[20] Currently, most ECG monitors can perform ST-segment analysis automatically with high sensitivity and specificity for detecting ischemia.

Despite appropriate lead selection and the use of automated ST-segment monitoring, perioperative ECG monitoring has important limitations. Visual inspection of the ECG on the monitor has low sensitivity in diagnosing ischemic changes, and automated ST-segment analysis depends on the computer's ability to set the isoelectric and J-point reference points accurately. During cardiac surgical procedures, the set points should be checked before and after bypass, especially persistent changes in heart rate, because the reference points chosen at the beginning of the case may not be accurate under conditions that may arise later.[21]

Arterial and Central Venous Pressure Monitoring (see also Chapter 36). Invasive arterial cannulation and monitoring comprise a standard of care for cardiac surgical patients. Patients' comorbidities often include labile hypertension, atherosclerotic CVD, or both. Furthermore, cardiac surgical technique frequently causes sudden, rapid changes in arterial blood pressure resulting from factors such as direct compression of the heart, impaired venous return caused by retraction and cannulation of the great vessels, and arrhythmias resulting from mechanical stimulation.[22] In addition, sudden, significant blood loss may induce hypovolemia and hypotension. Finally, during nonpulsatile CPB, noninvasive blood pressure recordings are not accurate. Intraarterial monitoring provides continuous, real-time, beat-to-beat assessment of arterial perfusion pressure and waveform throughout the cardiac surgical procedure. Having an indwelling arterial catheter also enables the frequent drawing of arterial blood for laboratory analyses.[22]

Although the radial artery is the most commonly accessed site, the femoral, brachial, ulnar, dorsalis pedis, posterior tibial, and axillary arteries can also be used. The pressures measured in the peripheral arteries are different from the central aortic pressure because the arterial waveform becomes progressively more distorted as the signal is transmitted down the arterial system.[22] Although the mean arterial pressure (MAP) measured in the peripheral arteries is usually similar to the central aortic pressure, this may change after CPB is initiated.[23] When cannulating a radial artery, one should consider the native state of the collateral circulation in the hand and the possible surgical use of a radial artery free graft as an arterial conduit. If a radial arterial graft is to be harvested, it is usually taken from the nondominant hand or arm; thus, the arterial line should be placed on the dominant side.

Central venous access is also standard of care during cardiac surgery. In addition to monitoring central venous pressure (CVP), central venous access provides a portal for intravascular volume replacement, pharmacologic therapy, and the insertion of other invasive monitors, such as pulmonary artery (PA) catheters. In addition, a CVP catheter can be used to measure the filling pressure of the right ventricle and estimate intravascular volume status.[22] Although the CVP does not directly reflect left-sided heart filling pressure, it may be used as an estimate of left-sided pressures in patients with good left ventricular (LV) function. Following trends is more useful than relying on an individual measurement.[22] In many patients, using a central venous catheter may offer a better risk-to-benefit ratio than using a PA catheter.[24] For the accurate measurement of pressure, the distal end of the catheter must lie within one of the large intrathoracic veins or the right atrium.[22]

An internal jugular vein is most commonly selected for catheterization because it provides ease of approach and optimal distance from the operative field. A femoral or subclavian vein can be considered as well, but groin access can be challenging in obese patients and may be inappropriate if femoral bypass cannula placement or vein graft harvesting is necessary. The subclavian approach is also imperfect because it is associated with an increased risk of catheter obstruction during sternal retraction.

The use of ultrasound is being rapidly adopted throughout the United States for facilitating the placement of central venous catheters and reducing the complications associated with them.[25] Although ultrasound-guided central catheter placement is easily accomplished and appears to improve patients' outcomes, concerns regarding the associated costs of the required hardware and training are reasons for the lack of universal adoption of this technique (Box 54.1).

Pulmonary Artery Catheterization. The PA catheter is a flow-directed catheter typically placed through an introducer in the central venous compartment via the internal jugular, subclavian, or femoral vein (see also Chapter 36). This catheter can measure PA pressure (PAP), CVP, and pulmonary capillary wedge pressure (PCWP). However, the PCWP can both overestimate and underestimate LV filling pressure (Box 54.2). Some PA catheters are designed with a thermistor to register blood temperature changes, which are used to calculate right-sided heart cardiac output (CO) or ejection fraction (EF) by thermodilution. PA catheters may also have oximetric capabilities to measure mixed venous oxygen saturation ($S\bar{v}O_2$). Thus, a PA catheter can be used to assess intravascular volume status, measure CO, measure $S\bar{v}O_2$, and derive hemodynamic parameters.[22]

BOX 54.1 Some of the Recognized Benefits of and Concerns About Ultrasound-Guided Central Venous Cannulation

Benefits*

Greater success rate on first attempt
Fewer overall attempts
Better access in patients with difficult neck anatomy (e.g., resulting from obesity or prior surgery)
Fewer complications (e.g., carotid artery puncture, anticoagulant-enhanced bleeding)
Visible vessel patency, anatomic variants
Relatively inexpensive technology

Concerns

Need for personnel to be trained to maintain aseptic technique when using sterile probe sheaths
Requirement for additional training
Inability to show surface anatomy
Potential loss of landmark-guided skills when needed for emergency central venous catheterization

*Ultrasonic guidance of internal jugular vein cannulation can be particularly advantageous in patients with difficult neck anatomy (e.g., short neck, obesity) or prior neck surgery, anticoagulated patients, and infants.

BOX 54.2 Conditions Resulting in Discrepancies Between Pulmonary Capillary Wedge Pressure and Left Ventricular End-Diastolic Pressure

PCWP > LVEDP

Positive-pressure ventilation
PEEP
Increased intrathoracic pressure
Non-West lung zone III PAC placement
Chronic obstructive pulmonary disease
Increased pulmonary vascular resistance
Left atrial myxoma
Mitral valve disease (e.g., stenosis, regurgitation)

PCWP < LVEDP

Noncompliant left ventricle (e.g., ischemia, hypertrophy)
Aortic regurgitation (premature closure of the mitral valve)
LVEDP > 25 mm Hg

LVEDP, Left ventricular end-diastolic pressure; *PAC,* pulmonary artery catheter; *PCWP,* pulmonary capillary wedge pressure; *PEEP,* positive end-expiratory pressure.

Modified from Tuman KJ, Carroll CC, Ivankovich AD. Pitfalls in interpretation of pulmonary artery catheter data. *Cardiothorac Vasc Anesth Update.* 1991;2:1.

The CO, the amount of blood delivered to the tissues by the heart, is of particular interest to cardiac anesthesiologists. The product of stroke volume and heart rate, CO is affected by preload, afterload, heart rate, and contractility. PA catheters capable of measuring CO continuously were introduced into clinical practice in the 1990s.[22] The correlation of continuous CO measurements with those measurements obtained by using the intermittent thermodilution method is good in physiologically and thermally stable prebypass and postbypass periods.

Continuous monitoring of $S\bar{v}O_2$ provides a means to estimate the adequacy of oxygen delivery relative to oxygen consumption.[22] Decreases in $S\bar{v}O_2$ may indicate decreased CO, increased oxygen consumption, decreased arterial oxygen saturation, or decreased hemoglobin concentration. If it is assumed that oxygen consumption and arterial oxygen content are constant, changes in $S\bar{v}O_2$ should reflect changes in CO.[22] However, London and colleagues found that continuous $S\bar{v}O_2$ monitoring did not lead to better outcomes than standard PA catheter monitoring.[26]

Pacing PA catheters are also commercially available. Electrode PA catheters include five electrodes for atrial, ventricular, or atrioventricular (AV) sequential pacing. Paceport PA catheters (Edwards Lifesciences, Irvine, CA) have a port for the insertion of a ventricular wire or of both atrial and ventricular wires for temporary pacing.

The risk-to-benefit ratio involved in using PA catheters has been a subject of controversy since the 1990s. Complications of PA catheter placement include those mentioned in the section on CVP placement, as well as transient arrhythmias, complete heart block, pulmonary infarction, endobronchial hemorrhage, thrombus formation, catheter knotting and entrapment, valvular damage, and thrombocytopenia.[22] In addition, a common complication is incorrect interpretation of the data obtained from the PA catheter, with resultant incorrect treatment of the patient.[27] Schwann and colleagues published a large, international, prospective observational study showing that using a PA catheter was associated with a more frequent risk of a composite mortality and morbidity outcome than using a CVP alone in patients undergoing CABG surgery.[24] Smaller observational trials have also associated the PA catheter with increased morbidity and decreased survival in cardiac surgical patients.[28,29]

Currently, the trend in the United States is to be selective in deciding which patients may benefit from a PA catheter, especially with the widespread use of transesophageal echocardiography (TEE). Absolute contraindications to PA catheter placement include tricuspid or pulmonic valvular stenosis, right atrial (RA) or right ventricular (RV) masses, and tetralogy of Fallot.[22] Relative contraindications include severe arrhythmias and newly inserted pacemaker wires (which may be dislodged by the catheter during insertion). Clearly, patients undergoing low-risk cardiac surgical procedures can be managed safely without PA catheter placement.[22] However, many cardiac surgeons and anesthesiologists still use the device in high-risk cardiac operations and in patients with right-sided heart failure (HF) or pulmonary hypertension, particularly to assist in postoperative management (Box 54.3).

BOX 54.3 Possible Clinical Indications for Pulmonary Artery Catheter Monitoring

Major procedures involving large fluid shifts or blood loss in patients with:
Right-sided heart failure, pulmonary hypertension
Severe left-sided heart failure not responsive to therapy
Cardiogenic or septic shock or multiple organ failure
Hemodynamic instability requiring inotropes or intraaortic balloon counterpulsation
Surgery of the aorta requiring suprarenal cross-clamping
Hepatic transplantation
Orthotopic heart transplantation

Modified from Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era.* 6th ed. St. Louis: Saunders; 2011:435.

Transesophageal Echocardiography. TEE is used in many, if not most, cardiac surgical procedures in the current era. See Chapter 37 for a thorough discussion of this extraordinarily valuable diagnostic and monitoring modality.

Central Nervous System

The incidence of overt postoperative stroke after isolated CABG decreased significantly from 1.6% in the year 2000 to 1.2% in the year 2009, despite the greater prevalence of diabetes mellitus and hypertension in the current era.[30] A more subtle entity, postoperative cognitive decline (POCD), or more recently termed delayed neurocognitive recovery as part of the postoperative neurocognitive disorders (PND), has also been described in numerous studies.[31] However, the measurement of POCD is complicated by variations in the tests used to assess cognitive function, the timing of these tests, and the diagnostic and statistical definitions of decline.[32] Furthermore, studies have shown that compared with nonsurgical and healthy controls, patients who undergo CABG have similar rates of cognitive decline 1 year postoperatively.[33,34]

BOX 54.4 Mechanisms of and Contributing Factors to Neurologic Lesions

Embolization

Hypoperfusion

Inflammation

Influencing Factors

Aortic atheromatous plaque
Cerebrovascular disease
Altered cerebral autoregulation
Hypotension
Intracardiac debris
Air
Cerebral venous obstruction on bypass
Cardiopulmonary bypass circuit surface

Cerebral hyperthermia
Hypoxia

From Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era.* 6th ed. St. Louis: Saunders; 2011:1070.

Risk factors for central nervous system (CNS) injury or dysfunction after cardiac surgery are listed in Box 54.4.[35] The most common cause is thought to be particulate or microgaseous emboli.[36,37] Other factors include cerebral hypoperfusion, particularly in patients with cerebrovascular disease, and the inflammatory response to surgery and CPB.[38,39]

Monitoring

Transesophageal and Epiaortic Echocardiography. TEE allows direct visualization of the first segment of the ascending aorta, the middle distal segment of the aortic arch, and a good portion of the descending thoracic aorta. However, the distal segment of the ascending aorta and the proximal

TABLE 54.1 Grading Aortic Atherosclerosis

Aortic Atheromatous Disease	Echocardiographic Findings
Grade 1	Normal or mild intimal thickening
Grade 2	Severe intimal thickening No protruding atheromas
Grade 3	Atheroma protruding <5 mm into the lumen
Grade 4	Atheroma protruding ≥5 mm into the lumen
Grade 5	Atheroma of any size with a mobile component

Modified from Béïque FA, Joffe D, Tousignant G, Konstadt S. Echocardiography-based assessment and management of atherosclerotic disease of the thoracic aorta. *J Cardiothorac Vasc Anesth*. 1998;12:206–220.

midportion of the aortic arch cannot be visualized well because of the interposition of the trachea and bronchi between the TEE probe and these aortic structures. Instead, epiaortic imaging with a handheld, high-frequency probe placed over the ascending aorta or aortic arch can be used to visualize aortic segments that are in the TEE probe's "blind spot."

The echocardiographic finding of atheromatous disease of the aorta has been linked to CNS injury in cardiac surgical patients.[40] Atherosclerosis of the ascending aorta is present in 20% to 40% of cardiac surgical patients, and the percentage increases with age. The severity of atheromatous disease of the aorta is a strong predictor of death and stroke after CABG (Table 54.1).[41] Using TEE to guide cannula placement or surgical technique significantly reduced the stroke rate in a series of 500 consecutive patients compared with controls in a statewide database.[42] Avoiding instrumentation of the ascending aorta (the "no touch technique") in patients with severe aortic atherosclerosis has been advocated.[43] The addition of epiaortic scanning of the ascending aorta increases the sensitivity of intraoperative echocardiography in identifying significant atheromatous disease in this segment of the aorta. Certainly, this combination of techniques is superior to surgical palpation in detecting such disease.[44]

Cerebral Oximetry. Cerebral oximetry uses near-infrared spectroscopy technology similar to that used in pulse oximeters. Light-emitting electrodes are placed on the patient's forehead, lateral to the midline, and over both frontal cortices. Because the skull is translucent to infrared light, and because oxygenated and deoxygenated blood have different absorption characteristics when exposed to infrared light of two different wavelengths, regional cerebral oxygen saturation (rSO_2) can be computed from the returning signal. The design of the cerebral oximeter enables it to measure change from the patient's own established baseline and to monitor both frontal lobes simultaneously.

The use of near-infrared spectroscopy has been studied in the perioperative setting; a relative decrease in rSO_2 to less than 80% of the preoperative baseline or to absolute levels less than 50% increased the incidence of adverse postoperative outcomes.[45,46] These outcomes include POCD,[47] stroke,[48] organ dysfunction, mortality,[49,50] and length of hospital stay.[51] A physiologically derived treatment algorithm for management of perioperative cerebral oxygen desaturation has been proposed (Fig. 54.3).[52] As noted by Murkin,[35] an important confounder in evaluating the role of monitoring cerebral oximetry is the efficacy of treatment for cerebral desaturation.

A baseline rSO_2 that is low even though the patient is breathing supplemental oxygen (absolute value ≤50%) is an independent risk factor for 30-day and 1-year mortality.[53] A baseline rSO_2 could act as a refined marker for preoperative risk stratification and help clinicians identify patients who require more intensive monitoring and care in the postoperative period.[53,54]

Transcranial Doppler. Transcranial Doppler (TCD) involves the ultrasonic interrogation of blood flow velocity through the middle cerebral or common carotid arteries as an indirect measure of cerebral blood flow.[45] The technology has been used extensively as a research tool. For example, in conjunction with cerebral oximetry, TCD has been used to delineate the limits of cerebral autoregulation during CPB.[55] TCD can also detect cerebral emboli. Contrary to previous information, an association between TCD-detected emboli and POCD is questionable.[56,57]

A primary limitation of TCD technology has been its inability to discern gaseous from solid emboli.[45,56] Other general limitations of TCD technology include the following: (1) the quality of information is heavily user dependent; (2) accuracy requires stable and precise probe placement, which can be quite cumbersome; and (3) information is affected by patient-related characteristics, such as skin thickness. These difficulties have limited use of this technology in the perioperative setting.[45]

Electroencephalography and Bispectral Index Monitoring. The electroencephalogram (EEG), recorded from multiple adhesive or screw-in scalp electrodes, represents surface cerebral cortical activity (see also Chapters 9 and 10). Awake patients produce a pattern of EEG readings that differs from the pattern produced by patients who are under anesthesia. Establishing a baseline and monitoring the changes from that baseline form the premise of EEG monitoring. Changes in the frequency of EEG signals (slower brain waves) and the reduction of wave amplitude may indicate changes in cortical neuronal function that warrant concern.

Multichannel EEG monitoring is not routinely used in cardiac surgery. However, a resurgence of interest in single- or dual-channel processed EEG monitoring, such as the bispectral index (BIS), has occurred.[45,58,59] The BIS has been studied as a means to monitor for intraoperative awareness, to reduce overall anesthetic consumption, and to provide information on cerebral perfusion. However, controversy surrounds the usefulness of BIS monitoring in reducing intraoperative awareness.[45,60-62] Similarly, the effectiveness of BIS monitoring in either guiding the safe reduction of anesthetic dosing or contributing to the success of fast tracking has not been demonstrated by randomized clinical trials in cardiac surgical patients.[58]

With respect to cerebral ischemia, sudden EEG changes during cardiac surgery and CPB can be attributable to correctable problems such as superior vena cava (SVC) obstruction or severe decrease in CO.[58] The latest iteration of the BIS monitor incorporates bilateral frontal EEG channels, which may increase its ability to detect unilateral

frontal ischemia, especially if anesthesia is stable, if the insult is sudden, extended, or located in the frontal area, and if the preoperative EEG was normal.[58,63] However, many variables may confuse EEG interpretation during cardiac surgery. These include hypothermia, the pharmacologic suppression of EEG signals, and interference produced by pump mechanics. In addition, the EEG measures only cortical activity, so ischemic or embolic injury that occurs below the level of the cortex may go undetected. Therefore, the EEG and derived indices are neither sensitive nor specific in detecting cerebral ischemia.[58]

SUMMARY. Currently, evidence-based recommendations cannot be made regarding the efficacy of treatment for abnormal values. Although not yet recognized as a clinical standard of care, neuromonitoring will likely continue to be the subject of significant research effort.

Renal System

Acute kidney injury (AKI) after cardiac surgery remains a significant cause of postoperative morbidity, increased cost of care, later development of chronic kidney disease, and short-term as well as long-term mortality.[59] Although the pathogenesis of AKI is multifactorial, control of some specific factors may limit its incidence in cardiac surgical patients. Bellomo and associates identified six major injury pathways of cardiac surgery–associated AKI: toxins (both exogenous and endogenous), metabolic factors, ischemia-reperfusion injury, neurohormonal activation, inflammation, and oxidative stress.[60]

Randomized trials of specific potential preventive measures for AKI after cardiac surgery are few. Certainly, all potentially nephrotoxic drugs should be avoided in the perioperative period (Box 54.5).[59,61] Hydration is, of course, a universally accepted component of strategies to prevent

contrast nephropathy.[61] Unfortunately, no pharmacologic strategy has definitive efficacy in preventing early AKI.[61] Atherosclerosis of the ascending aorta appears to be an independent risk factor for AKI.[60]

Intraoperative TEE should be used to identify patients at increased risk for thromboembolic phenomena.[60,61] Although observational studies have suggested a possible benefit of off-pump procedures and avoidance of aortic manipulation, definitive evidence is lacking.[60,61] For cardiac surgical cases that require CPB, the duration of aortic cross-clamping should be limited if possible, especially in patients who are at a higher-than-normal risk for renal complications, such as patients with preexisting renal insufficiency.[60] Hemodynamic instability should be addressed quickly, and intravascular volume should be maintained or rapidly restored.[60,61] Finally, perioperative hyperglycemia should be avoided.[60,61]

Clearly, definition of measures that may prevent AKI after cardiac surgery is needed.[60,61] The cost of this complication to the patient and to society is probably higher than previously thought.[59]

Endocrine System

Glucose Control. Hyperglycemia in surgical patients is a consequence of the inflammatory or stress response to the trauma of surgery. Components of this response include an endocrine response (i.e., increased production of counter-regulatory hormones such as cortisol, growth hormone, glucagon, and catecholamines) (Fig. 54.4), an immune response resulting in increased cytokine production, an autonomic response resulting in increased sympathetic stimulation, and altered insulin signaling. These changes increase glucose production, decrease glucose elimination during CPB, and induce insulin resistance, thereby causing hyperglycemia.[62]

All patients are at risk for developing hyperglycemia during cardiac surgery. Older patients, diabetic patients, and patients with CAD are particularly prone to perioperative hyperglycemia. Although cardiac surgery without CPB initiates a stress response, CPB increases this response manyfold.[63] The degree of hyperglycemia depends on several variables associated with the use of CPB, such as the pump prime fluid selected and the degree of hypothermia induced. Epinephrine and other inotropic drugs may contribute to hyperglycemia after CPB by stimulating hepatic glycogenolysis and gluconeogenesis.

Impaired fasting glucose blood levels before cardiac surgery and persistently increased glucose levels during and immediately after surgical procedures are predictive of longer hospital stay and increased perioperative morbidity and mortality in both diabetic and nondiabetic patients.[64,65] However, in diabetic patients undergoing cardiac operations, hyperglycemia may only partly explain the increased risk for adverse outcomes.[65] Immunologic abnormalities common to diabetic patients, such as decreased chemotaxis, phagocytosis, opsonization, bacterial killing, and antioxidant defense, also promote adverse outcomes by increasing diabetic patients' risk of infection.[66]

Glucose blood levels should be controlled, beginning in the preoperative period and continuing until discharge.[67] However, in a classic study, patients were randomly assigned to intensive intraoperative insulin treatment (to maintain glucose levels at 80-100 mg/dL) or to standard insulin treatment (to keep glucose levels <200 mg/dL).[68] Surprisingly, the investigators reported a statistically nonsignificant increase in the incidence of death and stroke in the group receiving intensive insulin treatment. Current Society of Thoracic Surgeons (STS) guidelines state that blood glucose levels should be kept lower than 180 mg/dL throughout the perioperative period.[69] Some cardiac surgical centers more aggressively administer continuous insulin infusions in an attempt to keep glucose levels lower than 150 mg/dL.

Thyroid Hormone. Fig. 54.5 shows the effect of thyroid hormone on cardiovascular hemodynamics.[70] Abnormal thyroid function ultimately affects cardiac function in many ways (Table 54.2). During cardiac surgery, the effect of CPB on thyroid hormone production is uncertain. Both increased and decreased levels of thyroid hormone can occur during or immediately after CPB. Free triiodothyronine (T_3), the biologically active form of the thyroid hormone, is frequently reduced in cardiac patients because of the reduced activity of the 5′-monodeiodinase responsible for converting thyroxine (T_4) into T_3 in peripheral tissues.[71] Patients with low T3 values are predisposed to low CO and therefore death as a complication of cardiac surgery. Patients should be profiled for T3 levels and labelled high risk if the levels are low preoperatively.[72]

Notably, hypothyroidism is more common in female than in male patients undergoing CABG.[73] Zindrou and associates noted a 17% higher mortality rate in women who underwent CABG while receiving thyroxine replacement therapy for hypothyroidism.[74] A review of the literature by Edwards and colleagues concluded that ensuring a perioperative euthyroid state in women with hypothyroidism who were undergoing CABG could be helpful in reducing the perioperative mortality of these patients.[75]

Hematologic System

Bleeding is the primary complication of cardiac operations that require CPB. In fact, 10% to 15% of blood product use in the United States is associated with cardiac surgery, and this percentage is increasing, largely because of

the increasing complexity of cardiac surgical procedures. Real-world data obtained from a large sample of patients and entered into the STS Adult Cardiac Surgery Database suggest that 50% of patients who undergo cardiac surgical procedures receive a blood transfusion.[76] Complex cardiac operations such as "redo" procedures, aortic operations, and the implantation of ventricular assist devices (VADs) require blood transfusion much more often than do simpler operations. Donor blood is viewed as a scarce resource that is associated with increased healthcare costs and significant risk to patients. Furthermore, perioperative blood transfusion is associated with worse short-term and long-term outcomes.[77,78] Hence, reducing bleeding and blood transfusions has become a major focus of quality improvement efforts in cardiac surgery.

Heparin as an Anticoagulant. Since its discovery by Jay McLean, MD, in 1915, heparin has stood the test of time and remains the primary anticoagulant used in cardiac operations that require CPB. The mechanism underlying heparin's anticoagulant effect centers on the heparin molecule's ability to bind simultaneously to antithrombin III and thrombin. Modern nomenclature refers to antithrombin III as antithrombin (AT). The binding process is mediated by a unique pentasaccharide sequence that binds to AT. The proximity of AT and thrombin, mediated by the heparin molecule, allows AT to inhibit the procoagulant effect of thrombin by binding to the active-site serine residue of the thrombin molecule.[79] The inhibitory effect of AT is increased 1000-fold in the presence of heparin. The heparin-AT complex can affect several coagulation factors, but factor Xa and thrombin are the most sensitive to inhibition by heparin, and thrombin is 10 times more sensitive to the inhibitory effects of unfractionated heparin than is factor Xa.[80]

Only approximately onethird of the heparin molecules in a dose of heparin contain the critical pentasaccharide segment that is needed for high-affinity binding to AT. Thus, relatively large doses are required to produce the anticoagulant effect necessary for CPB. In fact, dosing of heparin for CPB is somewhat empiric. After a baseline activated clotting time (ACT) is measured (the normal range is 80-120 seconds), a dose of 300 to 400 units/kg of heparin is given as an intravenous bolus. Commercially available assays are used for calculating the patient's dose-responsiveness to heparin in vitro. Some practitioners administer heparin at the dose that is indicated by such an in vitro dose-response assay. Subsequent heparin dosing for extracorporeal circulation (ECC) is targeted at maintaining ACT values longer than 400 to 480 seconds. Also available is a heparin concentration monitor that uses protamine titration analysis for ex vivo calculation of the whole blood heparin concentration. This result is often used as an adjunct to the ACT value in confirming an adequate heparin concentration for CPB. Unfortunately, ACT test results vary substantially with clinical conditions and the particular platform used for measurement. Thus, the evidence supporting the use of a threshold of 400 or 480 seconds is almost entirely anecdotal.[81]

The dose of heparin used in patients on CPB is based on early landmark work published by Bull and coauthors in 1975.[82] A small study that sought evidence of thrombin activity during CPB in nonhuman primates and pediatric patients found results supporting a safe lower limit for ACT of 400 seconds.[83] In 1979, Doty and colleagues proposed a simplified dosing regimen guided by ACT values without dose-response curves.[84] The data and recommendations from these few studies constitute the primary basis for current heparin dosing protocols.

Despite heparin's historic and continued role in anticoagulation for patients maintained on CPB, it is not a perfect anticoagulant. Intrinsic and extrinsic pathway coagulation occurs despite heparin administration, and platelets can still be activated by contact with bypass circuitry and by heparin directly.[85] Alternative anticoagulants are discussed briefly in the section on heparin-induced thrombocytopenia (HIT).

Monitoring of Anticoagulation. Using ACT to monitor the effectiveness of heparin is not an exact science. Tremendous variability is observed in patients' anticoagulation responses to a given dose of heparin; reasons for this variability include variations in levels of heparin-binding proteins and AT. Hence, ACT values correlate poorly with actual heparin concentrations. Nevertheless, since the publication of Bull and colleagues' early work,[82] ACT has been the mainstay of anticoagulation monitoring in cardiac operations that require CPB.

Many different ACT measurement devices are commercially available, and each uses a different platform for clot detection and endpoint signaling. However, they all involve the addition of whole blood to a tube or channel containing a contact-phase activator. The activator can be celite, kaolin, glass, or any combination thereof. The sample is warmed to 37°C before the measurement technique is performed. Clot formation occurs, and the measurement ends when a change in velocity, pressure, oscillation, electromagnetic

TABLE 54.3 Clinical Variables That Can Affect the Activated Clotting Time

forces, or even color is observed, depending on the particular platform of measurement.[85]

Several clinical variables can affect the ACT (Table 54.3). In addition to physiologic variations, the design of ACT measurement devices (which varies across their many manufacturers) also affects ACT normal and therapeutic values. ACTs also correlate poorly with whole blood and plasma heparin levels, and responses to heparin differ somewhat between adult and pediatric patients.[86] Some authors argue that, because of its poor correlation with heparin concentration, ACT alone is not an adequate monitor of heparin efficacy, and that simultaneous or adjunct monitoring of heparin concentration should also be used during CPB. Prolongation of ACT by non–heparin-related clinical factors, such as hypothermia, hemodilution, or quantitative or qualitative platelet abnormalities, is a well-documented phenomenon, and the anesthesiologist must understand these factors to determine whether it is safe to reduce the heparin dose when the ACT is prolonged. The poor correlation between ACT and measured heparin concentration also makes it possible that a dose reduction will render the heparin concentration inadequate, even when the ACT remains within an acceptable range.

Some point-of-care (POC) monitors, such as the Hepcon HMS system (Medtronic Perfusion Systems, Minneapolis, MN), use a protamine titration assay to calculate the heparin concentration. Despotis et al. suggest that monitoring and maintaining heparin concentration—and thus giving larger doses of heparin—actually protect the hemostatic system and may decrease transfusion requirements.[87] However, other investigators have not been able to confirm that higher doses of heparin confer better hemostatic protection; markers of ongoing coagulation are essentially the same whether traditional ACT monitoring or heparin concentration monitoring is used.[88] The 2018 STS, Society of Cardiovascular Anesthesiologists (SCA), and the American Society of ExtraCorporeal Technology (AmSECT) Guidelines state: "Use of heparin concentration monitoring in addition to ACT might be considered, for the maintenance of CPB, as this strategy has been associated with a significant reduction in thrombin generation, fibrinolysis, and neutrophil activation. However, its effects on postoperative bleeding and blood transfusion are inconsistent (class IIb, Level of Evidence B)."[81] An additional recommendation includes: "During CPB, routine administration of heparin at fixed intervals, with ACT monitoring, might be considered and offers a safe alternative to heparin concentration monitoring. (class IIb, Level of Evidence C)."[81]

The high-dose thrombin time (HiTT) is a modification of the thrombin time that is designed to measure the high levels of heparin that are used during CPB.[81] Unlike ACT, the HiTT correlates well with heparin concentration, both before and during CPB, and it is not affected by hemodilution and hypothermia. As a measure of thrombin inhibition, the HiTT is a more specific test of heparin's effect on thrombin than ACT, and it appears to possess less artifactual variability. Preoperative heparin infusions do not affect HiTT values.[89]

Protamine and Reversal of Anticoagulation. Protamine, which has been in clinical use for as long as heparin has, remains the heparin reversal drug of choice in cardiac surgery. The protamine dose required to reverse heparin is somewhat controversial. In the first published study to examine this question, Bull and associates chose a dose of 1.3 mg protamine for every 100 units of heparin to provide a slight excess of protamine from a projected needed amount of 1.2 mg for every 100 units of heparin.[90] Protamine is usually administered according to the total amount of heparin given (i.e., 1-1.3 mg protamine per 100 units of heparin). This method may result in luxuriant protamine doses, which reduce any theoretic or real risks of heparin rebound but may put the patient at higher risk for bleeding events because of the anticoagulant effect of protamine. Guidelines for the practice of anticoagulation in CPB recommend the following:

1. "It is reasonable to limit the ratio of protamine/heparin to less than 2.6 mg protamine/100 Units of heparin, since total doses above this ratio inhibit platelet function, prolong ACT, and increase the risk of bleeding (class IIa, Level of Evidence C)."[81]
2. Because of the risk of heparin rebound in patients requiring high doses of heparin and with prolonged CPB times, low-dose protamine infusion (25 mg/h) for up to 6 hours after the end of CPB may be considered as part of a multimodality blood conservation program (class IIb, Level of Evidence C).[81]

Protamine can also be administered at a dose calculated from the heparin concentration, which is measured by a protamine titration assay. Guidelines[81] do support this practice stating that "it can be beneficial to calculate the protamine reversal dose based upon a titration to existing heparin in the blood, since this technique has been associated with reduced bleeding[87] and blood transfusion" (class IIa, Level of Evidence B).[87] If the heparin concentration is not measured, the protamine dose can be graphically derived by plotting ACT values throughout the case and creating heparin dose-response curves. The amount of protamine used in this method is based on the circulating concentration of heparin in the patient at the time of reversal. Because, theoretically, no excess protamine exists, these patients may be at risk for heparin rebound and therefore may require additional protamine. In a small study conducted in patients undergoing valve surgery, administering protamine in two divided doses by titration resulted in a larger dose but reduced bleeding, presumably by treating heparin rebound.[91]

Unique Hematologic Considerations in Cardiac Surgery

Hematologic Effects of Cardiopulmonary Bypass. The hematologic effects of CPB are complex. Exposure of blood to the surfaces of the extracorporeal circuit is a profound stimulus for inflammatory system upregulation, and activation of the hemostatic system is a component of the normal inflammatory response. According to traditional models of hemostasis, ECC activates both the intrinsic and extrinsic coagulation pathways and directly impairs platelet function. Intrinsic pathway activation can occur by contact activation and the conversion of factor XII to factor XIIa on the various surfaces of the CPB circuit. The tissue factor generated from the wound and the circulating tissue thromboplastin combine to cause the extrinsic activation of coagulation by cell-mediated hemostasis, which involves tissue factor–bearing leukocytes and activated endothelial cells. Tissue factor pathway generation of thrombin has a primary role in CPB-associated hemostasis abnormalities (Fig. 54.6).[92]

In addition to activating both extrinsic and intrinsic coagulation pathways, CPB directly impairs platelet function through a variety of mechanisms. Platelets express on their surface numerous glycoproteins that serve as receptors for several circulating ligands, such as fibrinogen, thrombin, and collagen (Fig. 54.7). The components of the bypass circuit adsorb circulating proteins that can serve as foci for platelet attraction and adherence. These surface-bound platelets activate and release the contents of their cytoplasmic granules, which can then serve as localized sources of thrombin generation, or they may embolize to initiate microvascular thrombosis.

Fibrinolytic activity is also increased by CPB. Contact activation leads to the activation of factor XII, prekallikrein, and high-molecular-weight kininogen, which causes endothelial cells to produce tissue plasmin activator, and lysis of fibrin and fibrinogen ensues (Fig. 54.8).

The vascular endothelium is itself an active substrate that is sensitive to circulating mediators, and it expresses and releases anticoagulant and procoagulant factors. When exposed to hypoxia or inflammatory mediators during CPB, the endothelium responds and can induce a relatively prothrombotic state marked by tissue factor upregulation, accelerated platelet adhesion, and increased expression of leukocyte adhesion molecules (Fig. 54.9).[93]

Heparin Resistance, Altered Heparin Responsiveness, and Antithrombin. Heparin resistance is marked by the inability to raise the ACT to therapeutic levels after administration of the recommended doses of unfractionated heparin. Some investigators have defined heparin resistance as

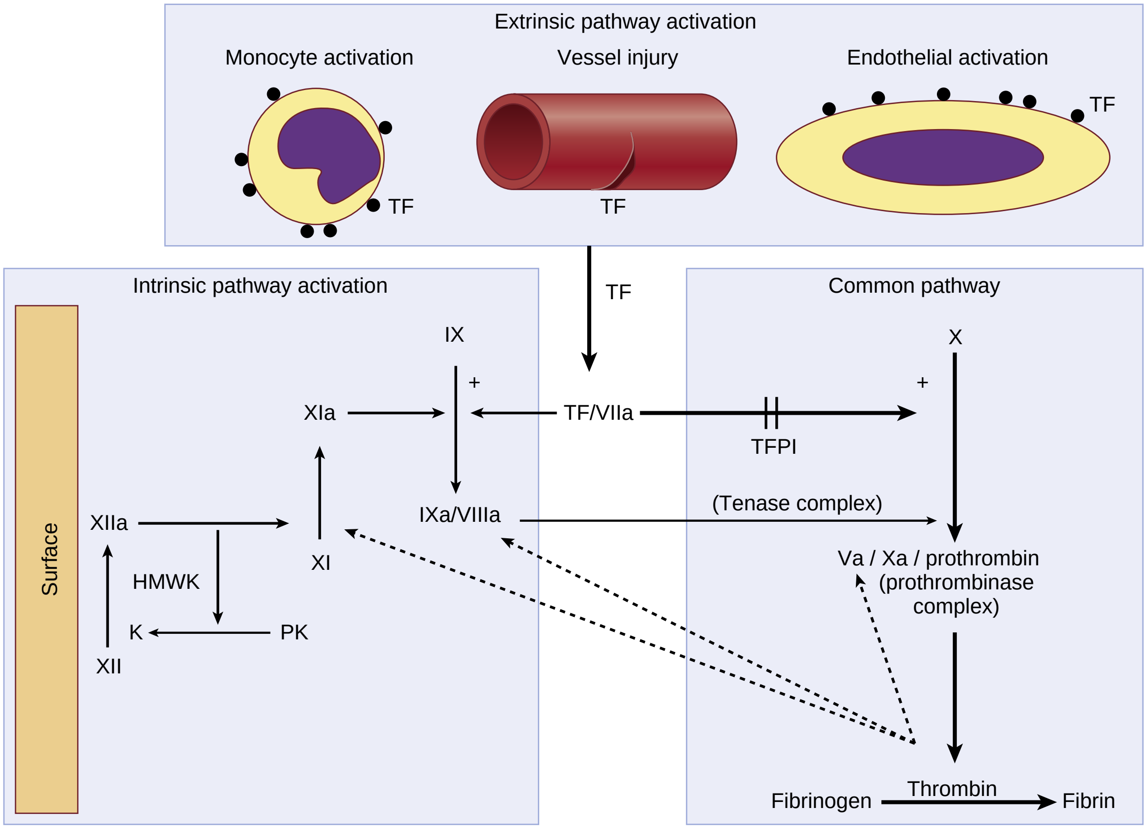

Fig. 54.6 Coagulation can be activated during cardiopulmonary bypass *(CPB)* by the intrinsic pathway, with surface adsorption and activation of factor XII, high-molecular-weight kininogen *(HMWK)*, and prekallikrein *(PK)*. Activation of the extrinsic pathway during CPB occurs with tissue injury, as well as with systemic inflammation, and it leads to monocyte and endothelial expression of tissue factor *(TF)*. TF, in combination with factor VIIa, starts the common pathway with the activation of factor X to factor Xa. Assembly of the prothrombinase complex on phospholipid surfaces leads to the production of thrombin and conversion of fibrinogen to fibrin. Tissue factor pathway inhibitor *(TFPI)* inhibits TF/VIIa. Thrombin can overcome this TFPI blockade by activating factors XI, VIII, and V and initiating activation of factor X by the tenase complex. *K,* Kallikrein. (From Kottke-Marchant K, Sapatnekar S. Fig. 54.7 Platelet activation by cardiopulmonary bypass materials is facilitated by rapid adhesion and conformational alteration of plasma proteins, including von Willebrand factor *(vWF)* and fibrinogen *(Fib)*. Platelets adhere to vWF through the glycoprotein *(Gp)* Ib/IX/V surface glycoprotein and to fibrinogen through the Gp IIb/IIIa receptor. Platelet adhesion stimulates intracellular signaling, which leads to degranulation of α granules (platelet factor 4 *[PF4]* and β-thromboglobulin *[βTG]*) and phospholipid reorganization with the formation of coagulation complexes and fibrin formation. Release of adenosine diphosphate *(ADP)* from dense granules and activation of the Gp IIb/IIIa receptor also occur and lead to the aggregation of platelets to the adherent layer. Because of shear forces, adherent and aggregated platelets can detach from the membrane and circulate in a degranulated state or form small microaggregates that lodge in the distal vasculature. Fig. 54.8 The fibrinolytic system results in the degradation of fibrin by plasmin. The intrinsic factors participate in the fibrinolytic system. Adsorption and activation of factor XII, high-molecular-weight kininogen *(HMWK)*, and prekallikrein *(PK)* occur on the cardiopulmonary bypass material surfaces. Kallikrein *(K)* and factor XIIa participate in the conversion of plasminogen to plasmin. Plasminogen is also activated by tissue plasminogen activator *(t-PA)*, which is released from endothelial cells, along with its inhibitor, plasminogen activator inhibitor-1 *(PAI-1)*. Plasmin degrades not only fibrin but also coagulation factors V and VIII *(fV and fVIII)* and platelet surface glycoproteins *(PLT GP)*. Kallikrein plays additional roles in the activation of complement and the angiotensin system, and HMWK accelerates fibrinolysis by stimulating endothelial production of t-PA. *FDP*, Fibrin degradation product; *α2PI*, α2 plasmin inhibitor. Fig. 54.9 Procoagulant endothelial cell activation. When endothelial cells are activated, they express tissue factor, which converts prothrombin to thrombin. Thrombin has multiple biologic actions: (1) stimulation of the release of von Willebrand factor and P-selectin, which cause platelet clumping and platelet, neutrophil, and endothelial cell adhesion; (2) conversion of fibrinogen to fibrin, the solid component of clot; (3) downregulation of the thrombomodulin/protein C and S systems; (4) release of tissue plasminogen activator *(t-PA)*, which catalyzes the formation of plasmin; and (5) release of thrombospondin, which binds to t-PA, prevents its breakdown by plasminogen activator inhibitor-1 *(PAI-1)*, and accelerates the formation of plasmin. *LPS,* Lipopolysaccharide. an ACT of less than the target (400-480 seconds) after 600 to 800 units/kg of intravenous heparin are administered.[94] Others have defined heparin resistance as an ACT of less than 400 seconds at any time during the course of CPB and heparin administration.[95] Heparin resistance can result from a congenital deficiency or abnormality of AT, which requires treatment with AT to restore heparin's anticoagulant properties.[96] More often, however, heparin resistance is the result of an acquired condition caused by the patient's disease status and physiologic state. Giving these patients larger doses of heparin may augment the ACT value; therefore, a more accurate term for describing these clinical findings is altered heparin responsiveness. This alteration can result from an acquired AT deficiency, increased levels of heparin-binding proteins, activated platelets, sepsis, or other conditions. In a small study of cardiac surgical patients stratified by their history of preoperative heparin use, altered heparin responsiveness was found in approximately 40% of the patients who had received preoperative heparin therapy.[96]

Reported risk factors for altered heparin responsiveness include AT levels less than 60% of normal, preoperative heparin therapy, and a platelet count greater than 300,000/μL. Ranucci and associates also found that low postoperative AT levels were predictive of a longer length of stay in the ICU,[97] and others have associated low AT levels with adverse myocardial outcomes.[98] Not all heparin resistance is AT mediated; thus, it is critical to understand the physiologic factors that contribute to the altered heparin responsiveness so that appropriate treatment can be instituted.[99-101]

The most common treatment for altered heparin responsiveness is supplemental heparin. In refractory cases, treatment with AT concentrate, or recombinant AT, in doses that are calculated to produce 80% to 100% AT activity, restores heparin responsiveness. AT supplementation is a class I indication for heparin resistance that is due to AT deficiency.[102] Thus the practice of replacing AT using this specific factor replacement is preferred over the use of plasma transfusion, which is no longer recommended due to the morbidity of allogeneic transfusion. When AT is used for this purpose, careful neutralization with protamine and attention to hemostasis are essential because AT augments the effect of heparin and thereby slightly increases postoperative bleeding.[102]

Heparin Rebound. Heparin rebound is clinical bleeding that occurs within approximately 1 hour of protamine neutralization. It is accompanied by coagulation test results indicating residual heparinization, such as a prolonged partial thromboplastin time (PTT) or thrombin time and increased anti-factor Xa activity. Mechanisms of heparin rebound include slow dissociation of protein-bound heparin after protamine clearance, more rapid clearance of protamine than of heparin, lymphatic return of extracellular sequestered heparin, and the clearance of an unknown heparin antagonist. Heparin rebound is rare, yet it is more likely to occur when the protamine dose is based on the residual heparin concentration at the end of CPB than when protamine is given as a ratio to the total heparin administered, because using this ratio usually results in a slight "overdose." With coagulation monitoring, heparin rebound is easily prevented or treated with supplemental protamine. A protamine infusion has also been successful in preventing heparin rebound in patients in whom heparin rebound is a risk.[103] These include cases in which high doses of heparin were administered or in whom CPB time was prolonged. Perfusion management guidelines suggest that a low dose protamine infusion (25 mg/h) for up to 6 hours after the end of CPB may be considered as part of a multimodality blood conservation program (class IIb, Level of Evidence C).[82]

Heparin-Induced Thrombocytopenia. HIT is an immune-mediated prothrombotic disorder that occurs in patients exposed to heparin. Antibodies form against the protein platelet factor 4 (PF4) when PF4 has formed a complex with heparin. Although PF4 is found in only trace amounts in human plasma and is stored in platelet α granules, the presence of heparin increases plasma PF4 concentrations 15- to 30-fold by displacing bound PF4 on endothelial cell surfaces. PF4 is also expressed on the surface membrane of activated platelets by membrane fusion with the α-granule membrane; thus, PF4 is exposed and available to bind with heparin. The resulting PF4-heparin complex on the platelet surface is recognized by a specific immunoglobulin G (IgG), which binds to the complex and leads to immunologically mediated platelet activation. Hyperaggregability of these activated platelets is the hallmark of HIT and is responsible for its prothrombotic complications.[104,105] Often a clinical score such as the 4 Ts score can be used to determine whether a heparin-platelet antibody test should be performed to diagnose HIT (class IIa, Level of Evidence B).[82] Diagnosis can be difficult in the postcardiac surgery patient and often the 4 Ts score is unreliable.

A common presentation in patients with HIT is a reduction in the platelet count to less than 100,000/μL or to less than 50% of the baseline count. The incidence of seroconversion after CPB and heparin exposure is quite frequent (20%-50%).[106] However, the reported prevalence of clinical HIT after CPB is only 1% to 3%.[107] Thus, the risk of HIT in cardiac surgical patients with postoperative seroconversion is less than 10%.

The strength of the immunologic response, not the mere presence of PF4 or heparin antibodies, may determine which patients are prone to HIT and are at risk for thromboembolic complications.[107] The presence of preoperative antibody, in addition to postoperative antibody, has been associated with increased morbidity after cardiac surgery.[108] This morbidity takes the form of gut ischemia, renal dysfunction, limb ischemia, and other prothrombotic events.

Management of the cardiac surgical patient with HIT must include a careful risk-to-benefit analysis. The likelihood that a patient has true disease and is at increased risk for a thrombotic event must be weighed against the risks posed by using an alternative anticoagulant to heparin. The urgency of the surgical procedure is also an important factor that can affect decision making. It is preferable, when possible, to defer the operation until antibody titers have become undetectable[82] or only weakly positive, which may occur after 90 days (class IIa, Level of Evidence C).[107] If surgical postponement is not practical, then other therapeutic options must be considered (Boxes 54.6 and 54.7). Currently, the direct thrombin inhibitors are used as the anticoagulants of choice. Hirudin and argatroban are approved by the U.S. Food and Drug Administration (FDA) for use in patients with HIT-related thrombosis.[109] The use of these drugs as anticoagulants for CPB is fraught with hemorrhagic complications. Bivalirudin has been approved by the FDA for use in percutaneous interventions and, because of its short half-life, has been favored as an anticoagulant for CPB in patients with HIT.[110-112] Guidelines suggest that in patients with a diagnosis of HIT and in need of an urgent operation requiring CPB, anticoagulation with bivalirudin is a reasonable option (class IIa, Level of Evidence B).[82] However, no drug other than heparin has FDA approval for specific use as an anticoagulant in patients undergoing CPB. Bivalirudin undergoes renal elimination. Therefore, in seropositive HIT patients who have significant renal dysfunction, anticoagulation for urgent operations requiring CPB can be accomplished with argatroban, plasmapheresis prior to heparin to remove antibodies, or heparin with concomitant antiplatelet agents to prevent platelet activation (tirofiban, iloprost) (class IIb, Level of Evidence C).[82] These latter two techniques have risk because they include heparin, and have been fraught with increased risks of bleeding. Boxes 54.6 and 54.7 summarize therapeutic options and alternative anticoagulant strategies for the patient with HIT whose operation cannot be deferred until seronegativity is documented. Fig. 54.10 delineates how each alternative drug inhibits factor Xa, thrombin, or fibrinogen.

BOX 54.6 Therapeutic Options for Anticoagulation for Cardiopulmonary Bypass in Patients With Heparin-Induced Thrombocytopenia

1. Ancrod
2. Low-molecular-weight heparin or heparinoid (test first)
3. Alternative thrombin inhibitor (hirudin, bivalirudin, argatroban)
4. Using a single dose of heparin, promptly neutralizing it with protamine, *and*
    a. Delaying surgery so antibodies can regress *or*
    b. Using plasmapheresis to decrease antibody levels *or*
    c. Inhibiting platelets with iloprost, aspirin and dipyridamole (Persantine), abciximab, or RGD blockers

In all cases:

1. No heparin in flush solutions
2. No heparin-bonded catheters
3. No heparin lock intravenous ports

No agent is currently indicated for anticoagulation in cardiopulmonary bypass.

RGD, Receptor glycoprotein–derived.

Protamine Reactions. Protamine is associated with several hemodynamic effects that can be categorized by their presentation and mechanism. Adverse reactions to protamine range from moderate hypotension to more profound and hemodynamically significant reactions that can increase in-hospital mortality risk.[113,114] The clinical presentation of these reactions serves as a starting point for understanding their mechanistic relationships. Commonly, these reactions are classified as type I, type II, or type III. A type I protamine reaction involves isolated hypotension, with normal to low filling pressures and normal airway pressures. This reaction is usually mild and responds to volume infusion, slowing of protamine infusion, and the gentle titration of vasoactive medications. Type II reactions include moderate to severe hypotension and features of anaphylactoid reactions, such as bronchoconstriction. Anaphylactoid reactions include protamine sensitivity reactions that are classically immunologic or allergic in that they are immunoglobulin E (IgE) antibody mediated. Nonimmunologic mechanisms may involve IgG antibodies

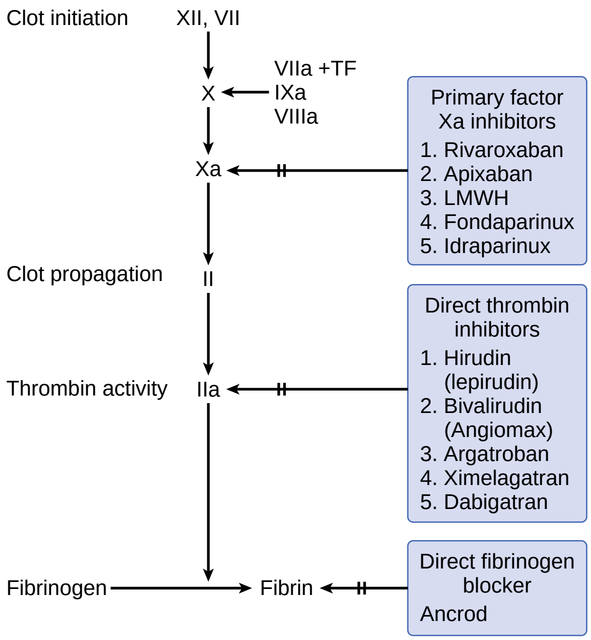

Fig. 54.10 Alternatives to heparin. Newer anticoagulants are shown in the boxes on the *right side* of the figure; these drugs inhibit factor Xa, thrombin, or fibrinogen. *LMWH,* Low-molecular-weight heparin; *TF,* tissue factor. (From Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era.* 6th ed. St. Louis: Saunders; 2011:968.)

or complement activation. Type III reactions are thought to be caused by large heparin-protamine complexes that lodge in the pulmonary circulation, cause the release of mediators, and result in severe hypotension and elevated PA pressures that may lead to acute RV failure. This is obviously a profound response, resulting in global cardiovascular collapse or necessitating the reinstitution of CPB because of intractable RV failure. Fortunately, catastrophic hypotension and intractable RV failure are relatively rare events on the spectrum of protamine reactions.[113]

Mechanistic explanations for protamine reactions include endothelial nitric oxide release, mast cell degranulation, and histamine release associated with rapid infusion. A study by Kimmel and colleagues found that neutral protamine Hagedorn insulin use, documented fish allergy, and a history of nonprotamine medical allergies were independent risk factors for protamine hypersensitivity reactions.[115] In this study, 39% of patients who presented for cardiac surgery had one or more of these risk factors. Other possible but unconfirmed risk factors include prior exposure to protamine, a history of vasectomy, decreased LV function, and hemodynamic instability.[115] The site of injection does not influence the incidence of protamine reactions.[116] Pretreatment with histamine blockade is not preventive.

The following principles summarize treatment options for patients at risk for protamine reactions:

1. Protamine should be administered slowly (i.e., over ≥5 minutes). Limit protamine dose to less than 2.6 mg protamine/100 units of heparin, since total doses above this ratio inhibit platelet function, prolong ACT, and increase the risk of bleeding (class IIa, Level of Evidence C).[82]
2. In patients with documented adverse events related to protamine, consideration should be given to *not* rechallenging the patient with protamine. Pharmacologic alternatives to protamine can be considered, or a decision can be made not to reverse heparin. Consideration may be given to using non–heparin-based CPB, performing off-pump coronary artery bypass (OPCAB) with an alternative to heparin, or, if heparin is used, administering nonprotamine heparin reversal drugs such heparinase, or simply waiting for heparin's effects to dissipate.
3. Hypotension associated with protamine reversal of heparin often is ameliorated by simply slowing or pausing protamine infusion while volume is infused through intravenous lines or the aortic cannula. Vasoactive medications, such as phenylephrine or ephedrine, use of calcium chloride, or increased inotropic support may be necessary.
4. Severe or intractable hypotension, with or without evidence of pulmonary circulatory involvement, bronchospasm, or overt RV failure, demands immediate aggressive attention, intervention, and planning for a potential return to CPB. Steps to consider include the following:
    a. Reheparinization to prepare the patient for a return to CPB and to reduce heparin-protamine complex size. If hemodynamics permit, a low dose of heparin (70 units/kg) may be tried first while supportive treatment continues, followed by a full CPB dose of heparin (300 units/kg) if it becomes necessary to return the patient to CPB. (class I, Level of Evidence C).[82]
    b. Inotropic support, either by infusion or by intermittent bolus administration, is warranted. Epinephrine and norepinephrine are acceptable options, and milrinone may be considered if the patient's hemodynamic status permits.
    c. If the patient's hemodynamic status allows, nebulized albuterol is helpful in the management of bronchospasm and elevated airway pressures.

Antifibrinolytic Therapy: Prophylaxis for Bleeding. Prophylactic use of antifibrinolytic drugs before CPB reduces bleeding and transfusion requirements in cardiac surgical patients in randomized trials and in multiple meta-analyses.[117,118] The most well-known antifibrinolytic drugs include the synthetic lysine analogues ε-aminocaproic acid (EACA) and tranexamic acid (TA) and the serine protease inhibitor aprotinin. Presumably, the blood-sparing effects of the synthetic drugs result from the inhibition of fibrinolysis by their binding to the lysine-binding sites on plasmin. This also has platelet protective properties because plasmin's antiplatelet effects are also inhibited by antagonist binding.
